through the GI tract in a net aboral direction (peristalsis), the rate of which influences GI transit times. In addition, the thin layer of smooth muscle in the lamina propria (muscularis mucosae) undulates the intestinal villi, thereby churning the unstirred layer of fluid that is associated with the brush border.

Transit time is the amount of time that elapses as a bolus of food or chyme traverses a particular region of the alimentary canal. In the mouth, transit time is determined by voluntary control of the length of time that is spent chewing food. When the food bolus passes to the pharynx and esophagus, transit time is governed by gravity and peristalsis. In humans, transit time through the pharynx and esophagus is about 6 s. Once in the stomach, transit times depend on the nature of the contents (Table 2.4 [12,66]). In the fasted state, the half-time for saline emptying from the human stomach is 12 min, while the gastric transit time for a full meal is about 4 h [11]. Generally, the various dietary constituents of a meal leave the stomach at varying times, with carbohydrates emptying first, proteins next, and fatty substances last. Liquids drunk with a meal often bypass the solids and enter the duodenum quickly [11]. Table 2.5 presents the ranges of transit times through various portions of the GI tract for each of the subject species. Transit times tend to be shortest in the stomach and longest in the large intestine. Additionally, liquids typically pass through the stomach more quickly than solids. Ingestion of a fatty meal, however, will delay significantly the emptying of stomach contents to the duodenum [10,24]. The fasting/fed state of an individual can also affect transit time, as demonstrated by the great differences in gastric emptying half-times for liquids given to fasted versus fed monkeys. For instance, after prolonged fasting the orocecal transit time is extended, probably because the body needs to absorb additional calories from the ingested material [67]. The amount of fiber in the diet not only influences transit time but also interferes with the access of some substances such as cholesterol to the absorptive surface [68,69].

Physiological status also influences transit time. For example, life stage (e.g., puppy vs adult) influences transit time in dogs. The mean orocecal transit time decreased as large breed puppies grew (Great Dane and Giant Schnauzer). This did not occur, however, in smaller breeds (Miniature Poodle and Standard Schnauzer). It is believed

that the decrease is due to the shorter gastric emptying times in large breeds during growth rather than to a faster rate of transport through the intestine [89,90]. In humans, orocecal transit times are significantly longer among older people compared to young adults, but transit time in the large intestine increases significantly only among women [85]. Because the dimensions of intestinal villi change such that the available absorptive surface area decreases with age [91], the increased transit time may be a compensation that improves (or attempts to realize) sufficiency of nutritional absorption. This same group of investigators reported that the overall GI transit time was significantly longer in women than in men at all ages.

2.7 LUMENAL CONTENTS

2.7.1 Physical and Chemical Nature of the Contents

The nature of the luminal contents in all species is altered as the contents traverse the alimentary canal. This alteration is due to the physical dispersion of ingested solid matter by chewing and the muscular activity of the stomach, the mixing of the ingested matter with imbibed fluid and digestive juices, the action of enzymes on GI contents, the absorption of fluid and materials from the lumen, and the addition of bacterial flora to the contents. There is a dramatic difference in the nature of the chyme that enters the duodenum of rats compared to that of humans [4]. Rat chyme contains many bacteria and has the consistency of a moist paste when entering the duodenum, whereas human chyme is watery and its bacterial content is negligible. The chyme of mice and rabbits is quite similar to that of the rat. The chyme of dogs, pigs, and monkeys is more similar to human chyme than to that of the rat. As chyme moves through the distal portion of the small intestine in all species, it begins to acquire a more viscous consistency, especially at the distal end of the ileum.

The daily volumes and constituents of digestive fluids secreted (under neuronal and hormonal control) by the various portions of the digestive tract and adnexal organs vary greatly based on the species and its physiological status. Estimates of these vary among publications, but the values summarized by Kararli [9] and DeSesso and Jacobson [4] are useful starting points for understanding the differences among species. The quantity and characteristics of these secretions can be altered in response to luminal contents. In addition to the intestinal secretions, water can move from the blood into the duodenum in response to a hypertonic meal, in order to maintain the isotonicity of luminal contents with that of plasma [11,12,24].

The pH of the luminal contents also varies widely among species (Table 2.6). As a general rule, however, the pH of luminal contents is the lowest in the stomach and increases as the chyme progresses distally through the GI tract, approaching neutrality. This modification in pH as the chyme travels through the GI tract is accomplished through the secretion of various acidic and alkaline fluids. In most regions of the digestive tract, the secretions are slightly alkaline, and the luminal contents exhibit a pH of 7–8 as chyme approaches the distal small intestine. The stomach is the lone exception to this general statement. The secretion of acid by the gastric mucosa results in acidification of chyme. In carnivores (including humans, pigs, and dogs) as well as the rabbit (an herbivore), the pH of the stomach is quite low (as low as 1–2 in humans), whereas the gastric pH of rodents (rats and mice) is only slightly more acidic (pH 3–5) than that of the skin. The moderate pH in the stomach of rodents is a consequence of the requirement for microfloral digestion of ingested material that begins before entry to the small intestine [9]. Animals with very acidic stomach contents begin the digestion of proteins therein and have no requirement for a large bacterial colony in their stomach. When chyme enters the duodenum, it is quickly neutralized by the alkaline (bicarbonate) secretion of the Brunner's glands [92]. The pH of chyme affects the ionization state of certain molecules and, therefore, can affect absorption.² Despite

²The GI tracts of most elderly humans exhibit the same pH characteristics as do those of younger adults, but there are notable exceptions. Some seniors exhibit elevated gastric pH or even achlorhydria (the inability to secrete gastric acid; Dressman *et al.*, 1989). Achlorhydria is often accompanied by delayed gastric emptying times.

TABLE 2.6 Range of pH Values Reported for Different Portions of the Gastrointestinal Tract for Seven Species of Animals^a

Species	Stomach		Small Intestine ^b			Large Intestine		
	Anterior	Posterior	Duodenum	Jejunum	Ileum	Cecum	Colon	Rectum/Feces
Mouse	4.5	3.1	—	—	—	—	—	—
Rat	4.3–5.1	2.3–4.0	6.5–7.1	6.7–6.8	7.1–8.0	6.4–7.2	6.6–7.6	6.9
Dog	1.5–5.5	1.5–3.4	6.2	6.2–7.3	7.5	6.4	6.5	6.2
Rabbit	1.9–2.2	1.9–2.2	6.0–6.1	6.8–7.5	7.2–8.0	5.7–6.6	6.1–7.2	7.2
Pig	1.6–4.3		6.0	6.2–6.9	7.5	6.3	6.8	7.1
Monkey	4.7–5.0	2.3–2.8	5.6–6.0	5.8–6.0	6.0–6.7	4.9–5.1	5.0–5.9	5.5
Human	1.5–5.0		5.0–7.0	6.0–7.0	7.0–7.4	5.7–5.9	5.5–7.5	6.5–7.0

^aThe range of values reported here are from the following Refs. 10,44,77,87, and 93–95.

^bSome studies reported pH values for segments 1, 3, 5, and 7 of the small intestine. For the purposes of this table, segment 1 was designated the duodenum, segments 3 and 5 were designated the jejunum, and segment 7 was designated the ileum.

its status as a carnivore, the pH of the GI tract of the dog presents some unique characteristics compared with humans. For instance, the fasting intestinal pH in dogs is higher than that of humans (7.3 in the dog vs 6.0 in humans [77]).

In addition to the pH gradient that exists along the linear axis of the GI tract, a pH gradient also exists from the center of the lumen moving radially toward the epithelial surface. The pH of the lumen is more acidic than the pH of contents at the epithelial surface. This is a function of the unstirred layer of water that is associated with the brush border [4] and the alkaline secretions of the intestinal epithelia [96]. Furthermore, this gradient may affect the rate of uptake of various substances, especially xenobiotics.

The contents of the alimentary canal are also altered by many enzymes found in the secretions of the digestive tract, integrated into or adhered to the cell surface membrane of small intestinal cells, and present within small intestinal cells. Many of these enzymes work to digest carbohydrates, proteins, and fats into readily assimilated molecules necessary to sustain life. Others are involved in the metabolism of xenobiotic compounds. Such compounds may be oxidized, hydrolyzed, and conjugated with large, polar molecules in order to facilitate their excretion. In some instances, however, this attempt at detoxification actually produces compounds that are more toxic than their parent compound. The presence and activity of all these enzymes may vary among species, with age and sex, along the length of the digestive tract and the height of the villus, with diurnal rhythm and diet, and among individuals [33,97–99].

The makeup of the lumenal contents is also changed through the progressive absorption of fluids, electrolytes, nutrients, and xenobiotics as chyme moves through the GI tract. Just as water can flow from the blood to the lumen in the case of hypertonic meals, water can rapidly be absorbed from the gut into the blood after hypotonic meals—again to maintain isotonicity of the lumenal contents with plasma. It should be noted that of the 8–9 L of fluid that enters the human upper digestive tract each day (~1.5 L of ingested fluid plus ~7 L of secreted digestive juice), only ~1 L enters

the large intestine and only about 100 mL of water is found in the daily output of feces [4].

2.7.2 Bile and Bile Salts

With regard to interspecies differences in secretions into the intestinal tract, it is important to note that among the subject species in this chapter, the rat is the only one that lacks a gallbladder. While the rat is unique in this respect among typical experimental animals, other common vertebrates, such as pigeons and horses, also lack gallbladders. Species that lack gallbladders do not concentrate bile; rather, bile flows into the lumen of the duodenum on a continuous basis. This means that bile continuously enters the rat duodenum as a dilute solution as it is made. By way of comparison, humans secrete from the gallbladder 2–22 mL of bile per kilogram body weight each day [41]. In contrast, rats secrete 48–92 mL of bile per kilogram body weight each day [20].

The daily flow rate of bile into the duodenum (normalized by body weight in kilograms) for five of the subject species is shown in Table 2.7. The table also lists the concentration of bile salts within the bile for five of the seven subject species. There is no clear relationship between the size of the species and its bile flow rate. Interestingly, the highest rate is found in the herbivorous rabbit.

Bile is a complex mixture of organic and inorganic materials of which the various bile acids are the major component. Bile acids are an extensive group of molecules that share a structural similarity to cholesterol but exhibit differences with regard to substituent side groups. Table 2.8 presents selected physical and chemical properties of bile and bile acids for six of the subject species in this chapter. Inspection of the table reveals that porcine bile has a bile acid composition and other properties that are most similar to human bile. Note that conjugation of bile acids to glycine or taurine is not an excretory pathway, but rather a means to enhance the enterohepatic recirculation of bile acids (see discussion in Section 2.8).

Interestingly, the composition of bile in hamsters, which is not considered in this chapter, is most similar to that of humans [100]. It is also noteworthy that rabbits have the most lipophilic bile of the animals considered, but they are unique in that about 80% of their bile acids are formed by bacterial flora [101].

TABLE 2.7 Comparison of Flow Rates and Composition of Bile from Seven Different Species^a

2.7.3 Bacterial Flora and Coprophagy

Bacterial flora populates much of the GI tract in all species and contributes to the lumenal contents. The mouth and pharynx have a rich and diversified bacterial population, although oral bacteria are not important in absorption. In rodents, large numbers of microorganisms are found in the stomach and intestines. In humans and rabbits, however, because of the low pH of gastric contents, microorganisms are virtually absent in the stomach and proximal small intestine. In fact, large numbers of bacteria are not encountered until chyme reaches the distal ileum and large intestine [11,94,103,104]. Bacteria are capable of metabolizing substances found in chyme and, thus, can alter constituents found in the luminal contents, which is particularly important in the case of ingested medicines and xenobiotics [105]. Differences between humans and rats with regard to the numbers and types of bacteria, as well as to their geographical location within the digestive tract, affect the site and extent of absorption of some substances [11,106]. Once chyme reaches the colon, bacteria are a major component of the lumenal contents. With the dehydration of chyme that occurs as it traverses the large intestine, bacteria eventually make up over 33% of the dry weight of the lumenal (fecal) content in the distal human large intestine [11].

Many species, especially rodents and rabbits, coprophagize (ingest feces) to aid the digestive process and to ensure absorption of essential components of their diets. This is exemplified by the rabbit, which has a unique digestive metabolism for a monogastric animal [107,108]. Rabbits defecate two types of fecal pellets: hard and soft [107,109]. The soft pellets are known as *cecotrophs* and are the pellets that are consumed by rabbits [110]. Cecotrophs are high in protein content and vitamin B complex [107]. Coprophagy also helps maintain a balanced, healthy population of flora. Impairment of coprophagy can result in deficiency of vitamins, as has been noted for over 80 years [111].

2.8 ENTEROHEPATIC RECIRCULATION

As previously stated, the hepatic portal system involves blood flow from the capillaries of the small intestine that drain to the hepatic portal vein, which flows into the hepatic sinusoids before reaching the heart. The movement of venous blood from the intestine along this specific route is referred to as the *enterohepatic circulation* (Fig. 2.12).

Figure 2.12 Enterohepatic recirculation. This cartoon illustrates the route followed by substances undergoing enterohepatic recirculation. Substances are absorbed from the lumen of the small intestine into the blood capillaries and are carried to the liver by the hepatic portal vein system (black arrows). Within the liver, the substances can be biotransformed by enzymes present in the hepatic cells, often being oxidized and/or conjugated. The biotransformed substances are subsequently excreted into the bile, which collects into the bile duct to empty back into the lumen of the duodenum (open arrows). There, the biotransformed substances may be acted on (usually deconjugated) by digestive enzymes, or, more commonly, by intestinal flora, to re-form the original substances that can then be reabsorbed into the intestinal capillaries, allowing the preceding steps to be repeated. *Source:* Reproduced from DeSesso JM, Jacobson CF. Food Chem Toxicol 2001;39:209–228, with permission.

Many absorbed substances are biotransformed by the hepatic parenchymal cells. Bio-transformation products tend to be larger and more polar than the parent compounds, which favors their excretion into the bile. Bile is eventually released into the duodenum. Because large, polar molecules tend not to be reabsorbed from the intestine, bile serves as a primary route of excretion for these molecules into the feces. Under certain conditions, however, some substances may be reabsorbed from the GI lumen, usually due to bacterial degradation of the metabolites in the intestinal lumen. Reentry of these substances into the enterohepatic circulation may be followed by another round of bio-transformation, followed by re-excretion into bile and then bacterial degradation and re-uptake. Enterohepatic recirculation can markedly affect the disposition of certain substances and is greatly affected by species-specific composition of bile acids [102].

A substance experiencing enterohepatic recirculation is able to maintain, or even increase, its systemic blood concentration, prolong its half-life in the blood, and even intensify its therapeutic or toxic effects. Alternatively, the compound may remain within the enterohepatic circulation (i.e., does not reach the systemic circulation), being absorbed from the intestine, taken to the liver, and excreted in bile over and over again. In such a case, systemic blood levels remain low, and any toxic effects outside the GI/enterohepatic tract are diminished, while effects within the tract may be increased [112].

2.9 CONCLUSIONS

Several parameters require consideration in any attempt (i) to define and model the events involved in the GI absorption of nutrients and nonnutrients and (ii) to extrapolate the results of these efforts between species. These include anatomical and physiological features of the GI tract (surface area, vascularity, transit time/motility, and enterohepatic recirculation). The physicochemical properties of the substance of interest and of the GI contents must also be considered. Variations in these parameters among different organs of the GI tract and among species affect the sites and rates of absorption, as well as the distribution and metabolism of the absorbed material. By far, the greatest amount of experimental information regarding GI absorption is available for the rat. Owing to similar small intestinal transit times, it is likely that the total amount of material absorbed by the small intestine after oral administration is similar between humans and rats, as has been concluded by others [113]. However, the rate at which ingested materials are absorbed differs between the two species. This is largely a function of the greater amount of surface area found in the proximal portion of the small intestine of humans. This led to the conclusion in our previous paper [4] that humans are likely five times more efficient at absorbing ingested materials than rats. This conclusion compares favorably to the report of Pappenheimer [36], who found that perfused jejunal segments of normal human subjects absorb fluids at a rate that is 5–10 times greater per unit area of mucosa than that of laboratory rats. It is also of interest to note that the oral absorption of a series of 43 drugs in dogs, which share many of the same physiological characteristics as humans, was found to differ significantly from the human [114], whereas the absorption of these substances in rats was much closer to that of humans [113]. The reasons for this remain unclear.

Not all parameters will be important for all chemicals, but a definitive knowledge of the role that each plays in the absorption of a particular substance of interest should

allow a quantitative description of the absorption process. Unfortunately, in many cases, the data necessary to evaluate the importance of these parameters is not available, and experiments must be done to measure their effects on absorption. Only by doing so can we effectively understand and accurately model the kinetics of ingested compounds. While the information provided in this chapter is not able to answer the question of which species is the most suitable model to study GI absorption, it is hoped that it will be useful to investigators who must select an animal model in which to test the pharmacological and toxicological effects of compounds for the purpose of extrapolating the findings to humans.

3.1 SUMMARY

When developing an oral drug, the drug discovery team's goal is to balance the physicochemical and molecular properties that enable a molecule to reach its final target, while maintaining sufficient clinical efficacy and acceptable toxicity.

First, solubility, dissolution rate, lipophilicity, pK_a (negative logarithm of the acid dissociation constant, K_a), and molecular weight (MW) are major physicochemical properties driving the absorption potential of a drug. Indeed, a molecule should be in a solution to permeate the intestinal membranes, and the rate at which the molecule gets into the solution impacts its ability to get absorbed.

Second, after oral administration, a drug encounters physical barriers before it reaches the blood stream. These barriers are the physiology of the gastrointestinal (GI) tract and various GI fluids.

Intestinal absorption consists of the sum of multiple processes. The drug's permeability is a major determinant of its ability to be absorbed in the intestine. Molecules within the "rule of 5" chemical space are usually absorbed through a passive process. However, intestinal transporters could either hinder or promote a molecule's absorption. As an example, the multidrug resistance efflux transporter, MDR1 (P-gp/ABCB1) has been shown to limit oral absorption of low permeable molecules. On the other hand, the peptide transporter PepT1 can promote intestinal absorption of peptidomimetic molecules. Finally, the small and large intestine express metabolic enzymes. Therefore, intestinal metabolism can limit a drug's oral absorption and lead to drug–drug interactions (DDIs).

A multiplicity of tools exists to study intestinal absorption; these range from *in vitro* systems to *in vivo* experimentation. These tools provide data with different degrees of granularity and with distinct human absorption predictability.

Finally, the food and drug administration (FDA) has developed guidelines to assess molecules' properties in terms of intestinal absorption and potential of DDI.

3.2 FUNDAMENTALS OF ORAL BIOAVAILABILITY

In pharmacokinetics, absorption is a process by which a given dose extravascularly (EV) reaches the systemic circulation. The dose could be given orally, subcutaneously, intramuscularly, or any other way different from a direct injection into the vascular system. The term oral “*bioavailability*” (F) is a parameter that is used in pharmacokinetics to quantify the ability of a compound dosed orally to reach the systemic circulation, after surviving any first-pass extraction. Operationally, the systemic F can be determined as described by the following equation: $F = \frac{AUC_{p.o.}}{AUC_{i.v.}} \cdot \frac{Dose_{i.v.}}{Dose_{p.o.}}$.

In this equation, $AUC_{p.o.}$ refers to the area under the curve (AUC) derived from an oral administration and $AUC_{i.v.}$ refers to the intravenous (i.v.) administration. Conceptually, F quantifies the success with which a compound overcomes the potential barriers to reach the systemic circulation. A compound with $F = 1$ (or 100%) indicates that a given oral dose produces an identical systemic exposure to that observed in the corresponding i.v. dose. In this case, the complete dose reaches the systemic circulation, the compound completely overcomes any barriers, and absorption is complete.

Furthermore, On the other hand, $F = 0.5$ (50%) indicates that in transit from the oral administration site to the systemic circulation, half of the compound is lost; in this case, the oral dose to systemic concentration relationship indicates that the oral dose must be twice that of an equivalent i.v. dose to achieve a similar systemic exposure.

Furthermore, two other parameters are often used to describe absorption: C_{max} , which represents the maximal concentration observed following oral dosing and T_{max} , which is the time at which C_{max} is observed. C_{max} gives an insight into acute exposure maximums that can be achieved following oral administration, and T_{max} provides an insight into the timescales of absorption—both of which can be critical for the determination of a safety margin.

Some advantages of the oral (p.o. for per os which means literally “by mouth” in Latin) dosing route are that it is the most convenient, well-tolerated, patient compliant, and cost-effective route of drug administration. A significant disadvantage of p.o. administration includes the multiplicity of complex processes that determine a compound's absorption from the gut into the systemic circulation. As a consequence, the processes governing absorption is a significant source of inter- and inpatient variability in a compound's pharmacokinetic profile [1].

For oral administration, oral $F(F_{oral})$ can be defined as follows:

$$F_{oral} = f_a \cdot F_g \cdot F_h \cdot F_l$$

where f_a is the fraction of the dose absorbed from the gut. Physical processes typically determine this process. The terms F_{gut} , F_h , and F_{lung} are the bioavailability of the compound in the intestine (g), liver (h), and lung (l), respectively (F_l is typically 1,

and) is generally ignored—lung is usually not a barrier to oral administration). In addition to the compound's physicochemical properties, biochemical activities, such as transport and metabolism, hinder a compound's ability to be orally bioavailable. The equation accounts for the various barriers that a compound may encounter en route to the systemic circulation from the gut. It is clearly seen that a lack of f_a or bioavailability in any one of the organs will yield $F_{\text{oral}} = 0$ and, subsequently, the absence of systemic exposure.

3.3 ORAL ABSORPTION IN DRUG DISCOVERY

After oral administration, a drug encounters physical barriers before it reaches the blood stream. These barriers are the physiology of the GI tract and various GI fluids. The drug's chemical structure and physicochemical properties determines its ability to penetrate these barriers and reach its final target.

3.3.1 Role of Physicochemical Properties

Multiple processes determine the exposure of a drug after oral administration, and each of these processes is mainly driven by the drug's physicochemical properties.

3.3.1.1 Solubility. Solubility is a critical parameter for absorption because the drug must be in solution to permeate the GI membrane. Solubility is the maximum concentration a solid compound reaches in a solvent matrix at equilibrium and is altered under various conditions. Solubility is mainly driven by physicochemical properties, chemical structure, dissolution rate, and the solvent matrix used. Therefore, in a lead optimization stage, we can improve solubility by modifying the molecule's physicochemical properties and chemical structure.

The most efficient and frequent strategy used by medicinal chemists to increase the solubility is to introduce ionizable groups. Others include reducing lipophilicity, introducing hydrogen bonding and polar groups, reducing MW, and introducing out-of-plane substitutions. Introducing ionizable groups comes at a cost, since this may hinder permeability.

Beyond the ionization state, other physicochemical parameters, which influence the molecules' solubility, are MW and lipophilicity. Lipophilicity is the tendency of a compound to partition into a nonpolar lipid matrix versus an aqueous matrix. Lipophilicity is commonly determined using $\log P$ from octanol/water partitioning. A trend has been shown with lipophilicity where, on average, the higher the $\log P$, the lower the solubility [2]. While neutral molecules have been shown to be more poorly soluble compared to ionizable molecules, when $\text{clog } P < 3$, the average solubility of neutral molecules approaches the average solubility of ionizable molecules. The same trend has been shown with MW: as MW increases, solubility decreases [2].

The ionizability of a molecule is driven, in turn, by its $\text{p}K_a$ and the pH of the matrix in which the molecule is in solution. For acids, as pH decreases, there is a greater concentration of neutral molecules and lower concentration of anionic acid molecules. The reverse is true for bases (Fig. 3.1). In addition, from a physiological stand point, the luminal pH changes along the GI tract and in the presence of food;

Figure 3.1 Percent formation of the ionized form of a weak acid over a pH range. (See color insert.)

therefore, solubility of acids and bases will vary in an opposite way, if their solubility is mainly driven by their ionization stage.

The drug discovery team will have to determine whether solubility or permeability is the rate-limiting step, and adjust the project strategy accordingly. Indeed, if solubility were the limiting absorption, introducing ionizable moiety would be the strategy of choice.

3.3.1.2 Dissolution Rate. The dissolution rate is the rate at which the molecule dissolves into a solvent from a solid form. Therefore, a molecule with a high dissolution rate will dissolve into solution quickly, leading to a quick absorption phase and increasing its chance to be absorbed within the GI transit time while its solubility remains constant. The dissolution rate depends on the particle size and compound physical and salt form. Reducing the particle size increases the surface area of the solid in contact with the solvent, which increases the dissolution rate.

The most frequent physical form in drug discovery is amorphous. An amorphous solid has no specific organization of molecules, whereas a crystal is a highly organized set of molecules. The amorphous form is often more soluble and less stable than the crystalline form. Therefore, caution is required when dosing poorly soluble amorphous compounds orally since these can precipitate in the GI tract to a more stable and less soluble crystalline solid form, leading to even poorer absorption.

To increase the dissolution rate, a salt form can be developed. Salts can stay in solution in a supersaturated state and delay the compound's precipitation. However, salts of weak acid or base can precipitate because they have converted to the free acid or base, leading to reduced intestinal absorption.

In conclusion, understanding the compound physical form and the size of the particles will help the team to understand if the dissolution rate is limiting molecules'

absorption. Furthermore, the team will determine whether additional formulation work could improve the molecule's dissolution rate.

3.3.1.3 Bioavailability. Lipinski *et al.* showed that particular physicochemical properties are associated with high or low oral bioavailability. They established the famous “rule of 5” that predicts that poor absorption or permeation is more likely when there are more than 5 H-bond donors, 10 H-bond acceptors, the MW is >500 g/mol and the calculated $\log P > 5$ [3].

Oral exposure is determined not only by the absorption through membranes of the GI tract but also by the extent to which organs just after absorption are able to extract these orally administered drugs. Therefore, gut and hepatic metabolism are key players in determining drug oral bioavailability. Varma *et al.* analyzed a set of 309 drugs where bioavailability, fraction absorbed (f_a), fraction escaping intestinal extraction (F_g), and fraction escaping hepatic extraction (F_h) were known. They determined which physicochemical property influences these parameters and how medicinal chemists and pharmacokineticists could play with these properties to enhance molecules' bioavailability [4]. They showed that f_a decreases with increasing MW (>500), polarity ($c \log D > -2$), polar surface area ($>125 \text{ \AA}^2$), total H-bond donors and acceptors (>9), and rotatable bonds (>12). Indeed, such properties limit the capability of small organic molecules to traverse lipid membranes. Molecules with a $\log P$ ranging from 1 to 3 are considered to be highly permeable. However, Varma *et al.* noted that high lipophilicity does not necessarily have a detrimental effect on f_a . Their analysis showed that the numbers of free rotatable bonds are negatively related with all three processes leading to a dramatic effect on bioavailability. They also noted that physicochemical properties that favor high f_a tend to be also associated with high rates of metabolism. For example, enough lipophilicity is needed to ensure good membrane penetrability, but too much will cause high hepatic and potentially intestinal extraction owing to metabolism.

This ionization state analysis of the compounds in the database indicated that bases are relatively less bioavailable, although they showed higher f_a than acids and neutrals, evidently because of higher first-pass effect [4]. Indeed, they explained that the higher first-pass effect of basic molecules can be attributed to their affinity for metabolic enzymes and relatively lower protein binding.

3.3.2 Paths to Intestinal Absorption

3.3.2.1 GI Tract Physiology. After oral dosing, the compound first encounters the buccal mucosa, where it can be absorbed. However, buccal or sublingual absorption is generally negligible. The drug is then ingested via the esophagus and arrives at the first part of the GI tract: the stomach. In the stomach, the drug is mixed with gastric acids, pepsinogen, and mucus secretions. Most drugs have limited stomach absorption since the stomach surface area is relatively small (about 1 m^2 [2]), the blood flow perfusion rate is low (150 mL/min) and the gastric emptying time is rapid ($0.5\text{--}1 \text{ h}$). Therefore, although the stomach's low pH (Table 3.1) favors absorption of acidic compounds, the absorption of acids is, in fact, faster in the small intestine. The small intestine consists of three consecutive sections: duodenum, jejunum, and ileum. The pH of each section increases successively and this progression of pH creates a gradient from the stomach to the ileum (Table 3.1). Absorption in the small intestine is greater because

TABLE 3.1 pH of the Gastrointestinal Tract Under Fed and Fasted State

GI Tract Section	pH, Fed	pH, Fasted
Stomach	3–7	1.4–2.1
Duodenum	5.2–6.2	4.4–6.6
Jejunum	5.2–6.2	4.4–6.6
Ileum	6.8–8	6.8–8
Colon	5.5–7	5.5–7

of the larger surface area (200 m [2]), the high blood flow perfusion rate (1 L/min) and the lengthy transit time (2–4 h). Since absorption is greater in the small intestine, the gastric emptying time can be a controlling step in the speed of drug absorption.

In the second part of the duodenum, the sphincter of Oddi allows the gall bladder to secrete bile into the GI tract. Bile is produced by the liver and stored in the gall bladder in humans, monkeys, dogs, and mice. Rats lack a gall bladder and this results in a continuous bile flow into the gut rather than the acute release of bile on gall bladder contraction. Bile, with its detergent-like properties, facilitates the solubilization and chemical breakdown of lipids, which explains why the bile is secreted in the presence of lipids in the duodenum. The presence of peptides and amino acids in the duodenum activates the secretion of pancreatic enzymes: amylases, lipases, and proteases. The pancreatic enzymes can hydrolyze some molecules that contain hydrolysable functional groups, resulting in the deactivation or activation of the drug in the GI tract. In addition, the pancreas secretes bicarbonates ion, which neutralize acid stomach secretions.

At the ileocecal junction, the small intestine connects with the large intestine. Although the large intestine transit time is long (7–20 h), drug absorption is limited mainly because of its small surface area (0.25 m [2]) and its lack of villi.

3.3.2.2 Permeability. Permeability is the rate at which a drug passes through a biological membrane and plays a major role in oral drug's bioavailability. Different mechanisms of membrane permeation exist: passive diffusion, active uptake and efflux, endocytosis, and paracellular flow.

3.3.2.2.1 Passive Diffusion. The predominant mechanism of absorption for commercial drugs is passive diffusion [3]. However, new chemical entities with physicochemical properties outside of the “rule of 5” might alter this trend.

Passive diffusion does not require energy and is driven by concentration gradient. Fick's law of diffusion best describes the parameters driving passive permeability (Eq. 3.1):

$$\frac{dQ}{dt} = \frac{DAK}{h} (C_{GI} - C_p) \quad (3.1)$$

dQ/dt = rate of diffusion

D = diffusion coefficient

K = lipid–water partition coefficient of drug in the biologic membrane

A = surface area of the membrane

h = membrane thickness
 C_{GI} = drug concentration in the GI tract
 C_p = drug concentration in the plasma

1. $(C_{GI} - C_p)$ represents the difference between free drug concentrations in the lumen and the free drug concentrations in the plasma. Because of the high GI blood flow rate, the drug is rapidly diluted into the blood stream after permeating the GI membranes. The high degree of drug dilution and the relatively high drug dose given orally (in the milligram range) are the bases for a large concentration gradient between the intestinal lumen and the blood stream.
2. K represents the lipid–water partitioning coefficient of a drug across the theoretical GI membrane. The physicochemical properties, such as, $\log P$, of the molecules significantly impact this parameter.
3. A represents the surface area of the GI membrane accessible to the drug. The larger the surface area of the GI tract, the faster the drug permeates. This explains why the duodenum that has the largest surface area is the principal GI region involved in drug permeation.
4. h represents the thickness of the theoretical GI membrane. It is assumed that it is a constant across the different GI regions.
5. D represents the amount of a drug that diffuses across a membrane for a given unit area when the concentration gradient is unity.

K , A , h , and D are constants for a given molecule with a given oral formulation. These parameters define the permeability of a drug and are summarized in one equation (Eq. 3.2). Furthermore, since the free plasma concentration is extremely low, C_p is considered negligible. Therefore, Equation 3.3 can be used as a surrogate for the Flick's law. This equation demonstrates that passive drug permeation through the GI membrane is a first order process.

Permeability equation derived from Equation 3.1:

$$P = \frac{DAK}{h} \quad (3.2)$$

$$\frac{dQ}{dt} = P(C_{GI}) \quad (3.3)$$

In addition to taking the free drug concentration into consideration, the ionization state of the molecules needs to be considered. Since a majority of molecules permeating through the membrane are in a neutral form, the efficacious gradient concentration is based on free neutral compound concentrations. Therefore, pH of the lumen and pK_a of the molecules impact the degree of gradient concentration. As an example, without taking blood flow into account, the amount of neutral form of an acidic compound in the duodenum lumen is much higher than that in the plasma, further driving the gradient concentration in the direction toward greater intestinal drug permeation. However, a formal electrical charge can be highly delocalized and therefore be less of a barrier than believed, especially when lipophilicity is sufficiently high.

3.3.2.2.2 Paracellular Permeation. Paracellular permeation and endocytosis are less frequent mechanisms of intestinal absorption. The paracellular pathway refers to the passage of drugs through the intercellular spaces. The paracellular pathway is governed by tight junctions (TJs). TJs or zonula occludens constitute the major rate-limiting barrier toward the paracellular transport of drugs. The dimensions of the paracellular space are between 10 and 30–50 Å, suggesting that solutes with a molecular radius exceeding 15 Å (~3.5 kDa) will be excluded from this uptake route. Transepithelial electrical resistance (TEER), measuring paracellular ion flux *in vitro* and reflecting the tightness of the intercellular junctional complex, are calculated on the basis of the serosal surface area rather than the real surface area of mucosa. As presented in a previous paragraph, the latter can vary dramatically depending on the section of intestine. In the small intestine, mucosal surface area is greatly amplified by villus projections and undulations. When TEER data are corrected for differences in mucosal surface area, the permeability of small intestinal and colonic epithelium is determined to be virtually identical [5,6]. Therefore, paracellular absorption is more likely to occur in the small intestine not because of leakier TJs but because of a larger mucosal surface area.

3.3.2.2.3 Endocytosis. Endocytosis is a constitutive process observed in most mammalian cells for the uptake of macromolecules, for example, lectins. It requires metabolic energy and it is a slow uptake mechanism resulting in a fusion of endocytic vesicles with lysosomes containing high levels of enzymatic activity. Endocytosis may involve specific receptors, for example, vitamin B12 receptor [7]. Endocytosis of compounds is believed to be minimal in the small intestine and is not a quantitatively significant mechanism for drug absorption in the intestine.

3.3.2.3 Effect of Food. Food can impact the drug intestinal absorption through several mechanisms, such as delay in gastric emptying, stimulation of bile flow, changes in GI pH, alterations in luminal metabolism, or interactions of the drug with food [8]. The extent of the food effect is dependent on the meal characteristics such as calorie content (low vs high calorie meals), nutrient composition (protein, carbohydrate-rich, or high fat meals), volume, temperature of the meal itself, and fluid ingestion.

Food also increases blood flow to the liver; therefore, changes in first-pass extraction may cause differences in bioavailability between the fed and fasted state. For compounds with saturable first-pass extraction, the bioavailability will increase with food intake, whereas the opposite will occur if hepatic enzymes are not saturated during first pass.

In addition to physiologic considerations, factors such as drug and food nonspecific binding, sequestration, or chemical instability can cause drug–food interactions. As an example, if a drug chelates with ions present in the ingested meal, drug dissolution, and/or absorption may be reduced. Furthermore, the meal itself may pose a physical barrier that prevents drug diffusion to the site of absorption resulting in decreased bioavailability. Also, drug instability, as a result of acid degradation, may be exacerbated by prolonged gastric residence after food ingestion.

For highly lipophilic drugs or large MW macromolecules, lymphatic uptake can be increased by the presence of a high fat meal, thereby lowering plasma drug levels.

Since the effects of food depend on the physicochemical properties of the drugs as well as its absorption and metabolism pathway, the extent of food effects are not

always predictable. However, it is well known that food effects on bioavailability are generally the greatest when the drug is administered shortly after a meal is ingested and when meals are high in total calorie and fat content. Hence, the FDA recommends the use of high calorie and high fat meals to study the effect of food on the bioavailability and bioequivalence of drugs. Furthermore, qualitative prediction of food effect is often possible based solely on the Biopharmaceutical Classification System (BCS) class of the drug. Gu *et al.* [9] were able to categorize 80% of a set of 92 drugs as having negative, positive, or no food effect based simply on their dose, solubility, and permeability.

3.3.2.4 Prodrug. A prodrug is any compound that undergoes biotransformation before exhibiting its pharmacological effects. Prodrugs can thus be viewed as drugs containing specialized nontoxic protective groups used in a transient manner to alter or to eliminate undesirable properties in the parent molecule. The major objectives of prodrug design are to improve chemical stability, solubility, oral absorption, metabolic stability and duration of action, tolerability, and tissue distribution.

A prodrug can be classified as carrier-linked or as bioprecursor. A carrier-linked prodrug contains a temporary linkage of a given active substance with a transient carrier group that produces improved physicochemical or pharmacokinetic properties and that can be easily removed *in vivo*, usually by a hydrolytic cleavage. A bioprecursor prodrug does not have a linkage to a carrier group, but results from a molecular modification of the active principle itself. This modification generates a new compound, the active principle, which can be transformed metabolically or chemically.

A prodrug activation occurs enzymatically, nonenzymatically, or sequentially (an enzymatic step followed by a nonenzymatic rearrangement). As much as possible, it is desirable to reduce biological variability, hence the particular interest in nonenzymatic reactions such as hydrolysis or intramolecular catalysis.

3.3.3 Intestinal Transporters

The activity of intestinal transporters is now widely accepted as an important determinant of oral drug absorption. Certainly, one major transporter has become a key area of research that continues to grow; the efflux pump ABCB1, also known as *P-glycoprotein* (P-gp) or MDR1. Because MDR1 can play a role in limiting oral absorption of certain drugs [10–12], this transporter has emerged as a potential determinant of drugs' oral bioavailability.

3.3.3.1 Efflux Transporters. Efflux transporters are present on many biological membranes, including the villus tip of the apical brush border membrane of gut enterocytes, and actively cause efflux of drugs from gut epithelial cells back into the intestinal lumen. Following oral administration, intestinal efflux transport processes present a significant barrier toward drug absorption. Efflux transporter proteins are from the ATP-binding cassette (ABC) family. Major transporters that have been shown to play a significant role in drug absorption are MDR1, and breast cancer resistance protein (BCRP; ABCG2), but MDR1 is the most characterized and well known [13].

3.3.3.1.1 P-glycoprotein/MDR1 Overview. Borst *et al.* [14,15] have postulated several likely physiological functions of MDR1. MDR1 protects against the entry of exogenous toxins ingested with food, evidenced by expression in the small intestine,

colon, and blood–tissue barrier sites. It also precludes entry of toxic compounds in the central nervous system and testis [16,17]. Recently, evidence has been reported to show how MDR1-mediated efflux can make intestinal secretion a potential mechanism for drug elimination [18,19]. It is well established that the substrate specificity of MDR1 is quite broad with respect to both chemical structure and size. The structural diversity of MDR1 substrates (and inhibitors) is so broad that it is difficult to define specific structural features that are required for substrates/inhibitors of MDR1. However, some of the properties that are shared by many MDR1 substrates include the presence of a nitrogen group, aromatic moieties, planar domains, molecular size ≥ 300 Da, presence of a positive charge at physiological pH, amphipathicity, and lipophilicity [20–24].

MDR1 possesses multiple drug-binding sites [25], and these sites are located in the middle of the lipid bilayer [26]. Since MDR1 removes substrates directly from the membrane, the primary determinant of substrate specificity is the ability of the drug to interact with the plasma membrane and the secondary determinant would be the ability of the drug to interact with one of the binding sites. This could explain the broad substrate specificity of MDR1 as well as why nearly all MDR1 substrates are lipophilic. Shapiro *et al.* [27] demonstrated that MDR1 possesses at least three positively cooperating drug-binding sites, an H site selective for Hoechst 33342 and colchicine, an R site selective for rhodamine 123 and anthracyclines, and another site for progesterone.

The nature of an interaction between two MDR1 substrates or a substrate and inhibitor may be unique. Therefore, caution must be exercised when trying to extrapolate how the substrate/inhibitor may interact with an untested substrate/inhibitor.

3.3.3.1.2 Impact of MDR1 on Absorption. During absorption, MDR1-mediated efflux activity can potentially attenuate the overall bioavailability of its substrates by multiple mechanisms. It can attenuate the rate at which its substrates permeate from gut across intestinal enterocytes (where MDR1 is located on apical membrane) into blood, thus, potentially delaying absorption time, reducing $C_{\max}$ and possibly reducing total exposure (AUC). Additionally, MDR1 efflux during intestinal absorption may enhance intestinal metabolic elimination, thus indirectly reducing the amount of compound able to reach the bloodstream [cf. “Intestinal Metabolism” (Section 3.3.4) paragraph below].

It has been shown through studies with *mdr1a* (–/–) mice and in clinical trials, that the mean absorption time, AUC and $C_{\max}$ following oral administration of MDR1 substrates is affected by directed efflux activity of MDR1 in the intestine [28–30]. For example, the plasma AUC values determined for a 10 mg/kg dose of paclitaxel observed in *mdr1a*(–/–) mice were indeed several times higher following oral administrations compared to values obtained in wild-type mice [31]. Oral bioavailability of MDR1 substrates such as tacrolimus, cyclosporin, and talinolol are known to be incomplete and variable in the clinic, as these are regulated by intestinal MDR1 and modulated by coadministered drugs, genetic polymorphisms, and disease states. In humans, duodenal MDR1 mRNA content was significantly correlated with the AUC and $C_{\max}$ of oral talinolol [32]. Also, the mRNA levels of MDR1, but not CYP3A4, correlated well with the concentration/oral dose ratio and the oral dosage of tacrolimus [33]. Long-term St John’s wort treatment decreased talinolol AUC with a corresponding increase in intestinal MDR1 expression, suggesting that St John’s wort has a major inductive effect on intestinal MDR1 [34].

MDR1-mediated efflux activity is an important determinant of digoxin oral absorption and this has been observed from DDI between digoxin and quinidine, and digoxin and rifampicin. Digoxin absorption is not influenced by first-pass metabolism and any changes to digoxin absorption are thought to be due to changes in the actions of MDR1. The interaction between orally administered quinidine and digoxin results in a dramatic enhancement in digoxin $C_{\max}$ and AUC [35–38]. Conversely, treatment with the MDR1 inducer rifampicin, has been shown to decrease digoxin $C_{\max}$ and AUC in humans [39]. In fact, it was shown that intestinally expressed MDR1 (induced by treatment with rifampicin) closely correlated with digoxin AUC in a negative fashion.

However, it has been shown that the *in vivo* intestinal absorption of highly soluble and highly permeable MDR1 substrates is dominated by their high permeability, and MDR1 plays a minimal role in the intestinal absorption of these compounds [40]. Cao *et al.* [40] reported that Verapamil intestinal permeability did not correlate with any gene expression patterns in the intestine, and suggested that MDR1 plays a minimal role in the *in vivo* intestinal absorption because of Verapamil's high permeability.

Therefore, for highly permeable compounds, a relatively high fraction absorbed can be expected when dissolution in the GI tract is not the rate-limiting step. On the other hand, for highly soluble and low permeable MDR1 substrates, MDR1 limits intestinal absorption in the distal segments of the small intestine but plays a minimal role in the proximal intestinal segments because of significant lower MDR1 expression levels in this region [41]. In conclusion, it is important to note that MDR1 efflux activity does not always predict a compound's absorption profile. Absorption is a highly complex multifactorial process in which MDR1 can play a part. The magnitude of the effect of MDR1 efflux activity on a compound's absorption profile, ultimately, depends on the MDR1 activity in combination with other critical factors such as solubility, permeability, and metabolism.

3.3.3.1.3 Other Efflux Transporters. In addition to MDR1, MDR related protein (MRP), also plays an important role in multidrug resistance of cancer therapy, and in affecting the behavior of other drug substrates. The MRP proteins are a relatively large protein family consisting of at least nine members. The amino acid sequences for MDR1 and MRP2 show only 15% similarity [42]. Other differences in their protein structure include different numbers of transmembrane domains (12 for MDR1 and 17 for MRP) and different orientation of their N-termini.

MRP2, previously referred to as *canalicular multispecific organic anion transporter* (cMOAT), is an important ATP-binding cassette transporter and consists of 1541 amino acid residues, encoded by ABCC2 gene. This apical membrane bound transport protein is highly expressed in the canalicular membrane, and is also present in the intestine, kidney, and the blood–brain barrier (BBB) [43–47].

BCRP, also known as *mitoxantrone resistance protein* (MXR), is the product of the ABC half-transporter gene ABCG2. BCRP expression is high in placenta and haematopoietic stem cells, while low in small intestine, colon, hepatic canalicular membrane, breast, venous, and capillary endothelium [48,49]. The physiological functions of BCRP include the extrusion of porphyrins from haematopoietic cells and hepatocytes, as well as the secretion of vitamin B2 (riboflavin) and possibly other vitamins (such as biotin and vitamin K) into breast milk [50]. BCRP shares some substrates as well as inhibitors with MDR1 and MRPs. BCRP has been reported to affect oral absorption, distribution across BBB and blood–placenta barrier, and hepatobiliary

elimination as well as milk secretion (see chapter titled Predicting Human Biotransformation Pathways of this volume and summary by Xia *et al.* [51]). Sulfasalazine low absorption from the small intestine is mainly due to MRP2 and BCRP but not MDR1. Although these efflux transporters hinder sulfasalazine intestinal absorption they enable its colonic targeting and therapeutic action [52]. Dahan *et al.* [53] have also shown that the combined effect of MDR1 and MRP2, but not BCRP, dominates colchicine transepithelial transport, leading to complete coverage of the entire small intestine and makes the efflux transport dominate the intestinal permeability process.

3.3.3.2 Uptake Transporters. Solute carrier (SLC) transporters are localized in the GI barriers. SLC transporters do not require ATP and transport the drugs according to their concentration gradient, thereby improving the intestinal absorption of a wide range of drugs [54]. Drug transporter-relevant SLC members in the intestine at the apical surface of epithelial cells include SLC organic anion transporter families (OATP subfamilies; gene SLCO), SLC peptide transporter family (PepT1; gene SLC15A1) and organic zwitterion/cation transporters (OCTNs; gene SLC22) [55]. While the impact of PepT1 on drug absorption is well established, the clinical significance of intestinal SLCs and OCTNs in drug absorption needs to be confirmed and established. Therefore, we will focus this paragraph on PepT1 transporter.

3.3.3.2.1 PepT1 Overview. The expression of PepT1 was found primarily in the small intestine, particularly in the duodenum [56,57]. The physiological substrates for proton-coupled peptide transporters are mainly cationic, anionic, or zwitterionic di- and tripeptides. Free amino acids and larger peptides are excluded. A peptide bond in the narrower sense is not an essential structural requirement for a substrate [58].

The uptake of PepT1 substrates is mediated by a proton gradient at the apical surface of epithelial cells, the system is known as a *proton-dependent cotransport system* [59]. Indeed, an inward proton gradient is established at the brush border membrane by the Na^+/H^+ exchanger, and then the influx of protons back into the epithelial cells is coupled by PepT1 to transport its substrates [60]. PepT1 has generally been characterized as a low affinity/high capacity transporter with a wide variety of compounds as substrates. Drug molecules transported by PepT1 include β -lactam antibiotics such as penicillins and cephalosporins [61,62], the anticancer agent bestatin [63], angiotensin-converting enzyme (ACE) inhibitors such as captopril, and the ester prodrugs enalapril and fosinopril [64]. Prodrugs of acyclovir and L-dopa can also be recognized and transported by PepT1 [65,66].

3.3.3.2.2 Impact of PepT1 on Absorption. It has been well established in recent years that PepT1 is a major player in the intestinal absorption of β -lactam antibiotics allowing their oral administration [60,67]. The transport protein accepts many β -lactam antibiotics as substrates because of its steric resemblance to the backbone of physiologically occurring tripeptides.

After oral administration, most angiotensin-converting enzyme (ACE) inhibitors such as captopril, enalapril, and lisinopril exhibit 30–100% absorption, likely because these molecules sterically resemble di- or tripeptide structures, thereby sharing an intestinal transport pathway [68,69]. However, Brandsch *et al.* [58], applying the two-electrode voltage clamp technique to *Xenopus laevis* oocytes expressing PepT1, concluded that the oral availability of ACE inhibitors that generate tiny inward currents

and display $K_i > 15$ mM cannot be explained by their interaction with the intestinal peptide transporter, especially at pharmacological doses, indicating other routes for absorption.

The human intestinal peptide transporter appears to be an effective target for increasing intestinal absorption of some small molecules. It is attractive as a prodrug delivery target because of its high capacity, broad substrate specificity, high expression in the intestinal epithelium, and low occurrence of functional polymorphisms [70,71]. Therefore, by using enzymatically hydrolyzable bonds in the preparation of PepT1-targeted prodrugs, it is possible to dramatically improve the systemic availability of poorly absorbed drugs, with limited systemic exposure to the intact prodrug. Han and Amidon described this general strategy as “peptide transport associated prodrug therapy” [72]. However, there are still relatively few examples of PepT1-targeted prodrugs in literature, with valacyclovir being the most widely studied [65]. Perkins and Abraham, at Eli Lilly, put in practice this approach and delivered the prodrug LY544344, demonstrating the utility of PepT1-targeted nonester prodrugs to overcome poor permeability and low bioavailability. This compound exhibits near-ideal prodrug properties, with good solubility and chemical stability, extensive and reproducible absorption across species, low concentrations of circulating nontoxic prodrug, and pharmacokinetic linearity across a wide dose range [73].

3.3.4 Intestinal Metabolism

The small intestine is the first site capable of metabolism of orally ingested xenobiotics. Therefore, it can play an important role in the first-pass metabolism of chemical compounds because both phase I and phase II metabolic enzymes are expressed [74,75]. Indeed, a number of therapeutic drugs such as cyclosporine [76], verapamil [77], and midazolam [78,79] undergo extensive intestinal first-pass metabolism.

Using Western blot analysis on microsomes prepared from mucosal scrapings from the duodenal/jejunal portion of 31 human donor small intestines, Paine *et al.* [80] demonstrated that CYP3A and CYP2C9 represent most intestinal cytochrome P450 enzymes, accounting for 80% and 15% of the total immunoquantified P450s, respectively. They also found that the expression of CYP3A4 varies along the length of the small intestine, decreasing from the duodenum to the distal ileum. The CYP3A4 content in the intestine is estimated to be <1% of that in the liver [80,81]. Furthermore, the greater overall weight of the human liver (1.5 kg) relative to that of the small intestine (0.7 kg), which when combined with the P450 concentrations and the microsomal protein contents provides for a greater overall metabolic capacity for the liver.

Interindividual variability in expression of phase I and II metabolic enzymes has been observed more frequently in small intestine compared to the same enzymes in the liver [82,83]. The mechanisms for the small intestinal variability in expression are not well known. One possibility is that the intestinal P450s are differentially induced by dietary and environmental factors [75].

As in liver, selective inhibition or induction of intestinal metabolizing enzymes either by dietary or environmental xenobiotics or by coadministered drugs has been identified as an important source of drug interactions and a contributor to variability in oral drug bioavailability [51,84,85].

Recent evidence has shown that MDR1 can play a role in determining the oxidative metabolism of its substrates that are also substrates of CYP3A. Indeed, several factors

have led to the observation that MDR1 and CYP3A4 may act in concert to determine the oral absorption and bioavailability of drugs [86–89]. In addition, MDR1 and CYP3A4 can be induced by many of the same compounds although it has recently been shown that these proteins are not coregulated [90]. It is well known that there exists a large degree of overlap between the broad substrate specificities of MDR1 and CYP3A4 [86], and it seems reasonable that the combined actions of MDR1 and CYP3A4 could contribute to the low oral bioavailability determined for many of these dual substrates. Studies involving cyclosporin A transport across Caco-2 cell monolayers have shown how the actions of MDR1 and CYP3A4 may act coordinately to enhance the attenuation of apical to basolateral transport of this drug. It was observed that cyclosporin A metabolism was much greater when the compound was transported in the apical to basolateral (absorptive) direction, than in the basolateral to apical (secretory) direction [91]. It was postulated that the reduction in the apical to basolateral flux of cyclosporin A, caused by apically directed MDR1 efflux, enhanced the exposure of the compound to CYP3A4, and thus a greater amount of metabolism was achieved [91].

In contrast to these findings, several pharmacokinetic models have been published that fail to predict an increase in CYP3A metabolism because of MDR1 efflux [92–95]. Recently, Badhan *et al.* [96] used a physiologically based model to confirm this hypothesis, demonstrating that intestinal drug metabolism is influenced directly by drug concentrations within the enterocyte, which is governed by the degree of MDR1-mediated drug efflux and drug permeability through the enterocytes. For drugs possessing apparent permeabilities in excess of 15×10^{-6} cm/s, increasing efflux ratio was predicted to result in an increase in CYP3A drug clearance by up to 12-fold in the distal intestine.

3.4 TOOLS AND METHODS TO ASSESS DRUG INTESTINAL ABSORPTION

A multiplicity of *in vitro* and *in vivo* tools are used to study intestinal absorption, providing data with different degrees of granularity and with distinct human absorption predictability.

3.4.1 *In Vitro* Tools

3.4.1.1 Permeability. One of the key parameters in predicting and understanding both GI absorption and the ability of a compound to cross cell membranes in general is permeability. For drug dosed orally, the membranes of most interest to the pharmaceutical industry are those in the GI tract, and for central nervous system (CNS) compound the, BBB. It is difficult to perform measurements on these complex membranes directly so a variety of *in vitro* models have been utilized over the years to gain an understanding and estimation of how a compound may cross biological membranes *in vivo* [97].

The most simplistic measure of permeability is lipophilicity. The general trend indicates that highly lipophilic molecules are likely to be more permeable. However, the scale of measurable lipophilicity is relatively compressed, which results in very little resolution of permeability for compounds that are structurally similar, and the process of crossing a membrane is too complex to be described by lipophilicity alone [98]. Thus, in an attempt to provide a more refined measure of permeability, cell monolayers

Figure 3.2 *In vitro* system used to determine drug permeability through a cell monolayer. (See color insert.)

grown on membrane supports were introduced in the 1990s [99]. The most common cell monolayer is the Caco-2 cell line, which is a polarized human colonic cancer cell line that forms integral monolayers and TJs when grown for ~ 20 days. These cells can be grown in 6-, 12-, 24-, and 96-well plate formats, which lend themselves well to robotic automation for both seeding and feeding, and permeability measurements [100,101]. Transcellular permeability is the movement of the compound through the cell itself and is often referred to as *passive permeability*; it is the parameter of most interest at the early screening stage. The typical experimental setup for a Caco-2 permeability experiment is to measure the apparent rate of permeability (P_{app} in 10^{-6} cm/s) of the compound in both an apical to basolateral (A to B) and a basolateral to apical (B to A) direction after incubation at 37°C for a given period of time (Fig. 3.2). The relative rates of permeability in the A to B and B to A directions indicate the compound's permeability and subsequent influx or efflux ratio (B to A/A to B). The advantage of Caco-2 is that it is a well-established technique in academia and industry for high quality permeability measurements, but the culture of the cell line is expensive and manually intensive when used as a screen for permeability.

MDCK (Madine-Darby Canine Kidney) is a dog kidney cell line that has also been applied to permeability measurements [102–104]. Although this cell line requires 3 days of culture compared to 15–21 days for most Caco-2 models, it is still relatively expensive and requires cell culture expertise. It is also less physiologically relevant, as this is a canine kidney cell line and generally the permeability measured is used to estimate intestinal absorption in humans.

The realization that the pharmaceutical industry required a cheaper but higher throughput measure of permeability resulted in the introduction of the parallel artificial membrane permeability assay (PAMPA). PAMPA utilizes artificial membranes designed to “mimic” biological membranes such as the GI tract and the BBB [105–108]. Extracted or synthetic lipids are solubilized in a solvent and dispensed onto a membrane support to form a lipid membrane. The amount of compound that moves from the donor chamber to the acceptor chamber after a period of incubation is measured, along with the amount left in the donor chamber.

These measurements and other parameters characteristic of the experimental setup are used to determine the effective permeability, P_e , and the retention factor, R_f [107]. PAMPA is a cost-effective screen because it is a physicochemical measure of permeability that is performed in a 96-well plate and is very amenable for automation. Despite the fact that PAMPA is another step further away from a physiologically relevant measurement for *in vivo* permeability or absorption, it can be used in the pharmaceutical

industry as a primary screen for measuring the intrinsic permeability of thousands of compounds per week [105,108]. PAMPA does not provide information about whether a compound is a substrate for active influx or efflux transporters that could be determined using the Caco-2 cell line. However, if this type of information is important then it can be determined at a later stage when the compound shows potential as a new drug candidate. PAMPA does aid the chemist, as the output can be a simple measure of permeability that allows for clearer structure – activity relationships (SARs) and easier interpretation when attempting to design a more permeable series.

3.4.1.2 Efflux Transporters. Some *in vitro* systems of note that are commonly used to both identify transporter substrates and study their effects on cellular disposition include the Caco-2 cell model and transfected MDCK cells [109–114]. The efflux transporters show a polarized expression in each model (localization to either apical or basolateral membrane) [115,116]. Taipalensuu *et al.* investigated the expression and interindividual variability in transcript levels of multiple drug efflux systems in the human jejunum and compared the expression profiles in these cells with that of Caco-2 cells. They showed that the transcript levels of 9 out of 10 ABC efflux transporters correlated well between jejunum and Caco-2 cells but BCRP exhibited a 100-fold lower transcript level in Caco-2 cells compared with jejunum. They concluded that Caco-2 cell line is a useful model of jejunal drug efflux, if the low expression of BCRP is taken into account [117].

MDR1 is a common efflux transporter expressed naturally in Caco-2 cells. However, the MDR1 levels are different in Caco-2 cells from lab to lab and in the gut wall of patients. These differences make it difficult to extrapolate effects seen *in vitro* to those *in vivo* when considering permeability. Shirasaka *et al.* [118] developed a method to estimate the permeability of MDR1 substrate drugs in human intestine from the expression level of MDR1 in cell lines, and thus the possibility to predict oral absorption of those drugs. Although Caco-2 cells express major intestinal ABC transporters, the high cost of sustaining these in culture for two to three weeks versus the three-day requirement for MDCK, make the latter an attractive model to assess compounds' affinity to MDR1 or any other efflux transporter.

3.4.2 *In Situ* and *In Vivo*

Although *in situ* models are seldom used in drug discovery setting, these models, for example, *in situ* single-pass perfusion of the rat intestine, can provide useful mechanistic information. The drug concentration in the intestine is known and controlled and the subsequent barriers a compound has to cross to reach the portal blood circulation are identical in the *in situ* and *in vivo* situation, which definitely contributes to the reliability of the *in situ* model. However, these are labor intensive and low throughput systems. Therefore, the drug discovery team relies on *in vivo* pharmacokinetic studies to give a sense of the absorption profile of their molecules. Rat is normally used to determine molecules' bioavailability and the fraction absorbed. Comparing data on 98 drugs, Zhao *et al.* [119] showed that rat absorption is similar to human absorption in terms of percentage of dose absorbed. Therefore, evaluation of *in vivo* absorption in rats could be used as an alternative method to predict the extent of intestinal absorption in humans following oral administration. To explain the good correlation between human and rat absorption data further, Cao *et al.* [120] determined the expression of

all known transporters and metabolizing enzymes in both human and rat duodenum and colon. They found a moderate correlation for the expression levels of transporters in the duodenum of human and rat and no correlation for the expressions of metabolizing enzymes. These findings provide the molecular mechanisms for the similarity and correlation of drug absorption and explain the lack of correlation in bioavailability between rat and human [120].

Chiou *et al.* [121] conducted a retrospective evaluation of using dog as an animal model to study the fraction of oral dose absorbed of 43 drugs in humans. The correlation between mean fraction of oral dose of drugs absorbed in humans and dogs is relatively poor; absorption is generally better in the dog. Although the dog is commonly employed as the nonrodent preclinical species for studying oral absorption in drug discovery and development, one should exercise caution in the interpretation of data obtained [121].

3.5 FDA AND INTESTINAL ABSORPTION

3.5.1 BCS Classification

The Biopharmaceutics Classification System (BCS) is a scientific framework for classifying drug substances based on their aqueous solubility and intestinal permeability (Amidon *et al.*) [122]. BCS takes into account three major factors that govern the rate and extent of drug absorption from immediate release solid oral dosage forms: dissolution, solubility, and intestinal permeability. According to the BCS classification, drug substances are classified as follows:

- Class 1: High Solubility – High Permeability
- Class 2: Low Solubility – High Permeability
- Class 3: High Solubility – Low Permeability
- Class 4: Low Solubility – Low Permeability.

A drug substance is considered highly soluble when the highest dose strength is soluble in 250 mL or less of aqueous media over the pH range of 1–7.5.

The permeability class boundary is based indirectly on the extent of absorption, that is, the fraction of dose absorbed, of a drug substance in humans and directly on measurements of the rate of mass transfer across human intestinal membrane. Alternatively, nonhuman systems capable of predicting the extent of drug absorption in humans can be used (e.g., *in vitro* epithelial cell culture methods). In the absence of evidence suggesting instability in the GI tract, a drug substance is considered to be highly permeable when the extent of absorption in humans is determined to be 90% or more of an administered dose based on a mass balance determination or in comparison to an intravenous reference dose.

The BCS classification can be used to request a waiver from the FDA for *in vivo* bioavailability and/or bioequivalence studies for immediate release solid oral dosage forms.

3.5.2 FDA View on MDR1

Having developed guidelines for using *in vitro* metabolism studies to assess drug metabolism (specifically cytochrome P450)-mediated potential DDI, the FDA has initiated an effort to develop similar guidelines for transporter-mediated DDI (<http://www.fda.gov/oc/ohrt/transporter-guidelines.pdf>).

fda.gov/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm064982.htm). Reflecting on the availability of extensive literature and industry data on the role of MDR1 in DDI, the FDA has developed a more comprehensive guideline on MDR1-mediated DDI. The FDA acknowledged the role of other transporters in inhibiting or inducing drugs disposition but without proposing guidelines on how to study these transporters. The International Transporter Consortium (ITC) recently published a paper addressing this specific gap [123].

For details of the guideline and decision trees developed by the FDA, the reader is referred to the website: <http://www.fda.gov/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm064982.htm>.

The guideline discusses design of *in vivo* DDI studies including the choices of substrate and interacting drugs, labeling implications, decision trees for substrates and inhibition data, and how the *in vitro* assays should be run. To identify MDR1 substrates for *in vivo* drug interactions studies, the guideline proposes the following process (i) examining bidirectional transport of the test compounds in Caco-2 or MDR1-MDCK cell monolayers, (ii) selecting likely substrates based on an efflux ratio >2 , (iii) confirming MDR1 substrate activity by showing that specific inhibitors of MDR1 decrease the efflux ratio, and (iv) selecting compounds for *in vivo* MDR1-related interactions studies if transport of a test compound with an efflux ratio of >2 in these test systems is inhibited by MDR1 inhibitors.

To identify MDR1 inhibitors for *in vivo* drug interactions, the guideline proposes the following process (i) examining bidirectional transport of MDR1 probe substrates across Caco-2 or MDR1-MDCK cell monolayers, (ii) determining the ability of the test compound to decrease net flux ratio of a MDR1 probe substrate, (ii) determining K_i or $[I]/IC_{50}$ of the test compounds, and (iv) selecting compounds with K_i or $[I]/IC_{50} > 0.1$ for *in vivo* drug interaction studies with a MDR1 substrate such as digoxin.

3.5.3 Recommendations from the International Transporter Consortium

The ITC comprises industrial, regulatory, and academic scientists with expertise in drug metabolism, transport, and pharmacokinetics [123]. The consortium was formed to address transporter-related questions from pharmaceutical scientists involved in drug development. They identified which transporters, based on current knowledge, are well-established determinants of pharmacokinetics; discussed methodologies to characterize drug–transporter interactions using *in vitro* and *in vivo* studies; and proposed recommendations that are important for drug development scientists in guiding preclinical and clinical studies of transporter-mediated drug interactions [123].

The consortium focused its work on a set of seven transporter proteins based on compelling evidence that they are involved in drug absorption, disposition, and/or drug drug interaction (DDI): OATP1B1, OATP1B3, OCT2, OAT1, OAT3, MDR1, and BCRP. MDR1 and BCRP are transporters proteins playing a key role in the absorption of new chemical entities (NCEs). For details of the ITC recommendations and decision trees, the reader is referred to the ITC paper [123].

In summary, to identify MDR1 and BCRP substrates, the ITC broadened the FDA drug interaction guidance and decision tree to include both MDR1 and BCRP. The ITC also recommends that when an NCE is identified as MDR1 or BCRP substrates, preclinical and clinical information should be assessed to determine whether a clinical

in vivo DDI study is warranted. In particular, the relative contribution of the transporter-mediated pathway to the overall clearance of the drug is the primary determinant of whether an inhibitor will have a major effect on the disposition of the NCE.

A NCE is considered to be a potential MDR1 and/or BCRP inhibitor if the net flux ratio of a MDR1 (or BCRP) probe substrate is decreased in the presence of the NCE using a bidirectional transport assay. Zhang *et al.* [124] proposed that drugs exhibiting an $[I]_2/IC_{50} \geq 10$ should be evaluated to determine whether intestinal MDR1 or BCRP inhibition occurs *in vivo*. In that publication, $[I]_2$ is the theoretical maximal GI NCE concentration after oral administration and calculated as the highest clinical dose (mg) in a volume of 250 mL. Using this approach, a drug with MW of 500 Da and an *in vitro* IC_{50} value of 10 μ M will have a $[I]_2/IC_{50}$ value >10 at a dose of ~ 12 mg or greater. Recently, using data from 26 digoxin DDI clinical trial and applying statistical analyses of binary classification and receiver operating characteristic (ROC), Cook *et al.* [125] revised cutoff values and ratio of $[I]_2/IC_{50} > 5$ were identified to minimize the error rate, a reduction of false negative rate from 36% to 9%.

The ITC discussed the characteristics of an NCE that would trigger an *in vitro* interaction study with a specific transporter: the physicochemical properties of the drug and the organ(s) involved in its clearance. In addition to *in vitro* data, human pharmacokinetic property of an NCE is also important in assessing the likelihood of a clinical transporter-related DDI.

ACKNOWLEDGMENTS

4.1 INTRODUCTION

Drug distribution describes the process by which a drug moves between the blood and various tissues (e.g., muscle and fat) or organs (e.g., brain). It is an integral part of ADME (absorption, distribution, metabolism, and excretion), which encompasses the complete fate of a drug when it enters the body and further background is provided in Section 4.2. Many factors can influence the ability of a drug to distribute in the body, including physiochemical and physiological factors, which are discussed in Sections 4.3 and 4.4, respectively. Uptake and efflux transporters also have an important role in drug tissue distribution as discussed in Section 4.5. Methods to investigate distribution continue to evolve and are employed *in vivo*, in both animal and human studies and in more sophisticated *in vitro* methods. Dosing of subjects with radiolabeled drugs is common and can be coupled with analytical techniques such as microdialysis, magnetic

resonance imaging (MRI), and positron emission tomography (PET). Classical and current *in vitro* and *in vivo* methods to investigate drug distribution are reviewed in Sections 4.6 and 4.7. Different models employed in the calculation of drug distribution from data are also outlined in Section 4.8. Finally, examples of the clinical implications of drug distribution are presented in Section 4.9.

4.2 BACKGROUND OF DRUG DISTRIBUTION

Drug distribution is an important part of a larger pharmacokinetic picture known as *absorption, distribution, metabolism, and excretion* (ADME), which has become integral in understanding and explaining drug effects. ADME is the interplay between absorption, distribution, metabolism, and elimination. Drug distribution describes the process by which a drug moves between the blood and various tissues (e.g., muscle and fat) or organs (e.g., the brain). Many factors can influence the ability of a drug to distribute in the body, including physiochemical and physiological factors and the contribution of transporters. When a drug is administered intravenously, or absorbed after oral dosing, it will rapidly circulate through the body in the bloodstream. A complete circulation of the blood typically takes about 1 min, and after this time, a drug will begin to distribute into tissues [1]. Factors that can affect the ability of the drug to distribute into tissues include water and fat solubility. A drug that is more water soluble will tend to stay in the blood or interstitial spaces, whereas a fat-soluble drug may concentrate in fatty tissues. Drugs can also be limited in their ability to penetrate into tissues depending on their ability to cross barriers, such as the blood–brain barrier (BBB) or placental barrier. Drug binding to plasma proteins can also affect its ability to distribute. Bound drug is not able to distribute into tissues; only the fraction unbound (free) moves into tissues and determines the pharmacodynamics or efficacy of the drug.

4.3 MULTIPLE PHYSIOCHEMICAL FACTORS INFLUENCE DRUG DISTRIBUTION

Cell membranes form the barriers between all the compartments of the body. There are four main ways in which small molecules and drugs can cross membranes and gain access to the different body compartments. First, they can diffuse directly through the lipid, they can diffuse through aqueous pores formed by special proteins in the membrane, they can combine with a transmembrane carrier protein, and, finally, they can transverse the membrane by pinocytosis. Of these four, diffusion through the lipid and transport via carrier-mediated mechanisms are the most important in terms of the disposition of drugs, including both paracellular and transcellular distribution. The aqueous pores in membranes are too small (ca. 0.4 nm) for most drugs to pass through, and pinocytosis is generally more important for the transfer of macromolecules (such as insulin) but not for small molecules. Significant advances in identifying and understanding transporters for xenobiotics have been made in recent years, and it is estimated that at least 5% of all human genes are transporter related [2]. This indicates the importance of transport across barriers in normal physiological processes. Transfer via carrier-mediated mechanisms is dealt with in more detail in Section 4.5, and this

discussion will therefore concentrate on factors that influence the passive diffusion of drug molecules through the lipid membrane.

4.3.1 Lipophilicity, pH, pK_a , and Ionization

The ability of drugs to cross membranes depends on their solubility in the membrane (determined by the partition coefficient of the drug between the membrane lipid phase and the aqueous phase) and the diffusion coefficient. There is therefore a close relationship between the lipid solubility of a drug and its ability to permeate a cell membrane. As a result, lipid solubility is a major determinant of the pharmacokinetics of a drug, and, for example, its absorption from the intestine, ability to transverse the BBB, and rate of renal elimination can to a large extent be predicted from its lipid solubility.

Many drugs are either weak bases or acids and can exist as both ionized and non-ionized forms, and as such their lipid solubility depends to a large extent on the pH of the environment. The dissociation constant, pK_a , can be determined by the Henderson–Hasselbalch equation, and this relationship can be used to predict the extent of ionization of weak acids and bases in different pH environments. For a weak base, the relationship is

$$pK_a = pH + \log \frac{[\text{ionized form}]}{[\text{nonionized form}]}$$

and for a weak acid,

$$pK_a = pH + \log \frac{[\text{nonionized form}]}{[\text{ionized form}]}$$

For both weak acids and bases, the ionized form is not generally lipid soluble, and cannot cross membranes, unless by a specific transporter mechanism. On the other hand, the lipid solubility of the nonionized form depends on the structure of the drug, and many nonionized drugs will permeate rapidly. However, there are exceptions to this and among them are polycationic aminoglycoside antibiotics, which as a group are not well absorbed orally and do not penetrate into the BBB or into most other body fluid compartments. Elimination of these drugs is almost exclusively by glomerular filtration, and 50–60% of a therapeutic dose is excreted unchanged by patients within 24 h [3].

Drugs have a wide range of pK_a values, and the values found among a selection of common drugs are depicted in Table 4.1. Where a pH difference exists between body compartments, then the extent of ionization of a drug would influence its ability to distribute within the body, with the ratio of ionized to nonionized drug being determined by the pK_a of the compound and the pH of the compartment fluid. An example of this is shown in Fig. 4.1, which illustrates the distribution of a weak acid, aspirin (pK_a 3.5), and a weak base, erythromycin (pK_a 8.8), between the stomach contents (pH 2), plasma (pH 7.4), and urine (at pH 6, which is the normal situation, and at alkaline pH 8). In this model, it is assumed that the nonionized drug will cross membranes and reach equal concentrations in each compartment, whereas the ionized drug will not cross at all. As a result, the total drug concentration in each compartment will be different, and an acidic drug will be trapped as an ion in the compartment with the highest pH. Theoretically, large concentration gradients can be built between compartments if there is a large difference in pH. However, in practical terms, this extreme situation does not

TABLE 4.1 pK_a Values for Some Acidic and Basic Drugs

Drug	pK_a value
<i>Bases</i>	
Chloroquine	10.8
Amphetamine	9.9
Atropine	9.9
Ephedrine	9.6
Desmethylinipramine	9.5
Propranolol	9.5
Chlorpromazine	9.3
Erythromycin	8.8
Dopamine	8.4
Morphine	7.9
Codeine	5.8
Diazepam	3.3
<i>Acids</i>	
Levodopa	2.3
Penicillins	2.7
Probenacid	3.4
Aspirin	3.5
Flufenamic acid	3.9
Warfarin	5.0
Phenobarbitone	7.4
Phenytoin	8.3

Bases are arranged in decreasing strength, acids are arranged in decreasing strength, with the strongest acids at the top, and the strongest bases at the top.

happen because fluids in body compartments are not static, and the constant flux of fluids between compartments reduces the concentration gradients. It is also of course unrealistic to assume that ionized drug is totally nonpermeant, and a small percentage will diffuse across membranes.

It is important to realize that for gastrointestinal (GI) absorption, a major overriding contributing factor is the enormous absorptive area of the villi of the small intestine compared with the smaller absorptive area of the stomach. For this reason, partition between different pH environments is not a major determinant of the site of absorption of drugs from the GI tract. Nevertheless, weak acids and bases are well absorbed from the intestine, while strong acids and bases are not, as discussed by studies such as that published in 1957 by Schanker and coworkers, which shows the absorption of a range of drugs across the rat [4] and human [5] stomach as a function of their pK_a values. They showed that strong acids, with pK_a of <2 , and strong bases, with $pK_a > 10$, are not well absorbed. The usefulness of the low oral bioavailability of a strong base is well demonstrated by the case of curare, a mixture of alkaloids found in various South American plants, used as an arrow poison by South American Indians. The effective constituent is tubocurarine, a quaternary-ammonium-containing compound, and the low

Figure 4.1 Theoretical partition of a weak acid (aspirin) and a weak base (erythromycin) between gastric juice, plasma, and urine (at the normal situation of pH 6 and at alkaline pH of 8). The numbers represent the relative partition compared with plasma, which has been taken as 100%, and illustrate the large differences in total drug concentrations that could result from the different fractions of ionized species present as a function of environment pH.

oral absorption of tubocurarine allowed it to be used safely in the hunting of animals for food. It was the earliest nondepolarizing neuromuscular blocking agent identified. Tubocurarine is not used clinically now in medicine being superseded by synthetic nondepolarizing blocking agents such as pancuronium, atracurium, and vecuronium, all of which are quaternary ammonium compounds with varying durations of action and low oral bioavailability [6].

The pH of the environment and the pK_a does, however, have important consequences for urinary excretion and for the distribution of drugs into the brain. If the urine becomes acidic then the excretion of weak acids is decreased, and that of weak bases is increased, and if urine becomes basic, this has the opposite effects. This means of enhancing the excretion of drugs by altering the pH of the urine has been used extensively to increase drug elimination in cases of overdose, particularly with aspirin and phenobarbitone, where alkalinization of the urine is an established clinical protocol to promote excretion of the weakly acidic drugs. This is discussed further in Section 4.9, with examples provided from the literature. In addition to altering urine pH, administration of sodium bicarbonate increases plasma pH and will increase the movement of weak acids from the central nervous system (CNS) into the plasma. In

overdose, administration of sodium bicarbonate would thus both increase the elimination of phenobarbitone and decrease its CNS toxicity. Conversely, the administration of a carbonic anhydrase inhibitor, such as acetazolamide, decreases plasma pH and causes weakly acidic drugs to become concentrated in the CNS, thus increasing their neurotoxicity.

4.3.2 Molecular Size

The rate of diffusion of a substance depends on its molecular size, the diffusion coefficient for small molecules being inversely proportional to the square root of the molecular weight. Although large molecules diffuse more slowly than small ones, because most drugs have molecular weights between 200 and 1000 kD, the effect of molecular weight does not have a major effect on their pharmacokinetics.

In terms of renal elimination, molecular weight is not an important factor as the glomerular capillaries allow molecules below a weight of about 20,000 kD to diffuse into the filtrate. Plasma albumin, with a molecular weight of about 68,000 kD, is virtually completely excluded, but most drugs with the exception of macromolecules cross the glomerulus freely. Molecular weight is, however, a major determinant controlling whether a chemical is excreted into bile. As a general rule, low molecular weight substances (<325 kD) are poorly excreted into bile [7]. Biliary excretion is regulated by the presence of the xenobiotic transporters present on the canalicular membrane of hepatocytes and has consequences for the biological half-life and toxicity of compounds. The role of transporters in drug distribution has been further discussed in Section 4.5.

4.3.3 Drug Delivery Systems

Particle size has a major effect on GI absorption, and this has been a factor in the standardization of formulations of pharmaceutical agents such as digoxin. For example, Lindenbaum *et al.* [8] demonstrated the marked variability in plasma concentrations seen in patients given four different tablet preparations of digoxin, and observations such as these contributed to the standardization of formulations. Digoxin has a low therapeutic index (maximum nontoxic dose/minimum effective dose), and control of circulating concentrations is crucial; problems with bioavailability contribute to unexpected clinical results [9], and capsule preparations proved to be more consistent than tablets [10]. The aim of clinical pharmacy is to deliver a drug for an appropriate time, within the therapeutic window, to a specific target, outside the systemic toxic concentration range. Conventional routes of administration, such as oral or injection, cannot always achieve this satisfactorily. Controlled release systems match the rate of drug delivery to its elimination, and thereby the concentration remains within the therapeutic range for most of a 24-h period. Today, such controlled release can be provided by a wide range of processes such as encapsulation, transdermal patches, bioadhesive systems, osmotic micropumps, microimplants, drug-eluting medical devices, and nanoparticles [11,12]. Polymers are employed to delay the dissolution of drugs and control their flux from the delivery system. This is usually achieved using a polymeric coating or matrix that degrades at a slower rate than the drug diffuses and releases. Copolymers of various ratios of lactic acid to glycolic acid [poly(lactide-co-glycolide)] are commonly used, the ratio controlling the rate of degradation [13]. The

development of delivery systems for small molecules, proteins, and DNA has taken an enormous step forward with advances in nanotechnology, and these are now making a significant contribution to the global pharmaceutical market. It is known that nanoparticles are taken up by cells more effectively than larger sized microparticles [14]. Nanodelivery systems can be designed with different compositions and biological properties, such as nanoparticles, dendrimers, nanocages, micelles, molecular conjugates, and liposomes, and these have been extensively investigated for drug and gene delivery systems [15]. The effect of particle size on the distribution of nanocarriers within the body has been established, and following intravenous administration, small particles (<30 nm) are eliminated by renal excretion [16], particles of 30–150 nm are taken up into the bone marrow, heart, kidney, and stomach [17,18]. Larger particles (>200 nm) are sequestered by the mononuclear phagocytic system and located mainly to the reticular endothelial system in the liver [19]. In addition, recently, the role of shape in the biodistribution of nanoparticles has been suggested [20]. In this context, Devarajan and coworkers [21] have described the effect of nanoparticle shape on *in vivo* distribution in rabbits and dogs. They have shown that irregularly shaped polymeric lipid nanoparticles evade macrophages and localize in the spleen opening up particle shape as a new possibility in controlling the disposition of nanoparticulate drug delivery systems.

4.4 PHYSIOLOGICAL FACTORS AFFECTING DRUG DISTRIBUTION

Drug distribution begins on absorption of a drug into the bloodstream. The various regions of the systemic circulation are perfused with blood through innumerable branching pathways, which are effectively arranged in parallel (Fig. 4.2) [1]. Distribution of drug occurs through the blood via the circulatory system. Blood is continually flowing from the heart to all areas of the body through arteries, to capillaries through organs and skin, reconverging into veins that return to the heart. The blood then travels to the lung for reoxygenation via the pulmonary circulation before returning to the heart to complete the process over and over again. Uninterrupted movement of blood is required for maintaining the supply of oxygen from the lungs and nutrients from the gut, as well as for the distribution of hormones, chemicals, including xenobiotics, water, and heat, and the delivery of waste for excretion [1]. The first stage of drug distribution is dependent on the cardiac output and regional blood flow to the various organs. Drug distribution is rapid to highly perfused organs, where the rate of blood flow is higher and these organs receive most of the drug, while distribution to adipose tissues, which are not so well perfused, is generally slower and drug concentrations are markedly less. Drug distribution is a reversible process in equilibrium so drug can move between organs and the circulation. Distribution of drug from systemic circulation to tissues is dependent on the interplay of the physiochemical properties of the drug such as lipid solubility, ionization, and molecular size (Section 4.3) and physiological factors such as binding to plasma proteins, rate of blood flow, susceptibility to passively diffuse, or to undergo active transport. It can be affected by local ionic and cellular conditions and special barriers such as biological membranes like the BBB and placental barrier. The drug exists in two forms in blood, the free form, which is active and available for biotransformation and excretion, or the bound form, which is usually pharmacologically inactive. The main physiological compartments, where drugs

are distributed, are the plasma (5% of body weight), interstitial fluid (16% of body weight), intracellular fluid (37% of body weight), fat (20% of body weight), specific organs (liver/kidney), as well as muscle, bone, and the CNS [22]. Additional factors can influence the ability of a drug to distribute, including the propensity of the drug to bind to plasma proteins. In the plasma, drugs generally bind to albumin although drugs can also bind to globulins (α , β , γ), α -1-acid glycoprotein (AGP) or lipoproteins. Since protein binding can have a large impact on drug distribution properties, Section 4.4.4 is devoted to covering this topic in more detail. The lipid solubility of the drug can also affect its distribution (Section 4.3.1). Additionally, the disease state itself can play an important role in determining the extent of distribution since disease-induced changes to many of the physiological parameters can markedly influence drug distribution. Many of these physiological factors are explained in further detail in subsequent sections.

4.4.1 Distribution Between Body Water

Drug distribution and dilution can occur between various organ compartments of water within the body and this information is sometimes useful for comparing the distribution of drugs with the volumes of the body water compartments by calculating a volume of distribution or V_d . The volume of distribution is a proportionality constant that relates the amount of drug in the body [dose (mg)] to the plasma concentration. $C_p = C_{p0}e^{-kt}$, where C_{p0} equals the initial plasma concentration and is a function of the distribution of the drug in the body:

$$V_d(\text{volume of distribution}) = \frac{\text{Dose (mg)}}{\frac{[\text{Plasma}] \text{mg}}{\text{mL}}}$$

V_d values can describe where drug is and do not necessarily correspond to real, physiological volumes. The V_d can reflect the ability of the drug to cross cell membranes (polarity), bind to plasma proteins (limits distribution), or bind to tissue proteins (increases distribution).

The amount of body water can be as much as 75% of the total body weight with the average being about 60% or around 44 L. This body water is distributed between four main compartments, the intracellular fluid (61%), interstitial fluid (27%), blood plasma (7%), and blood cell (5%) [22]. The V_d calculated for individual drugs can provide information on the extent of distribution between body water and tissues. Distribution between body water compartments is dependent on their volume and the barriers present, such as lipid membranes, binding to plasma proteins, and pH gradients that are encountered. Following entry into the body, regardless of route of administration, a drug has the propensity to be distributed into any one of these distinct body water compartments or to be sequestered within a cellular site. When a drug is administered directly to the bloodstream, it enters the plasma compartment. When a drug is absorbed, it passes through cell linings of the absorbing organ (skin, lung, or GI tract) into the fluids surrounding cells of the organ known as the *interstitial fluid*. The interstitial and intracellular fluids are in equilibrium with water and electrolytes, which move slowly into and out of cells in contrast to fast-moving blood. Drug can leave interstitial fluid by entering local tissue cells, entering blood capillaries (systemic circulation) or entering

Figure 4.2 Simplified schematic of the circulatory system showing direction of flow from the inferior vena cava and superior vena cava to the right atrium. From the right atrium, the blood will enter the right ventricle where it is pumped into the lungs oxygenated and returned to the left atrium where it is pumped by the left ventricle to the rest of the body and returned to the right atrium through the IVC and SVC as depicted above.

the lymphatic system. Drug can also enter transcellular fluids by passing through an epithelium. Examples of transcellular fluids are cerebrospinal fluid (CSF), aqueous humor of the eye, contents of renal tubules, urine in the bladder, glandular contents, synovial fluid in joints, pleural fluids, peritoneal fluids, bile, saliva, and GI secretions. Figure 4.3 shows a schematic of drug distribution after various routes of administration through to elimination. While these compartments of water (intracellular fluid, interstitial fluid, blood plasma, and blood cell/transcellular fluid) are important in describing the distribution of drugs, compounds rarely associate solely within them, but most often distribute among several compartments, often binding to cellular components as described in Section 4.4.8.

Figure 4.3 Pictorial representation of the disposition of a drug on administration. The theoretical bioavailability of the drug is highlighted below the route of administration on the left. Once the drug has been administered, it is absorbed and potentially distributed into various compartments of the body as detailed above. The methods for elimination will be dependent on a host of factors, including extent of distribution to eliminating organs such as the liver and kidneys. (See color insert.)

4.4.2 Drug Distribution Patterns

On entering the vascular system, a drug is distributed throughout body fluids, as described in Section 4.4.1, or into various tissues. The pattern of distribution that the drug exhibits reflects both the physiochemical nature of the drug and its ability to penetrate different membranes. The V_d can provide useful information on the type of distribution pattern displayed by a drug, and four different distribution patterns are recognized. Drugs exhibiting pattern 1 remain largely within the vascular system. This would encompass drugs such as dextran with a V_d in the region of 3–5 L, which approximates the volume of plasma [23]. Drugs that are distributed throughout the body water and not limited to the vascular system exhibit pattern 2 and demonstrate a V_d of around 30–50 L. Xenobiotics that exhibit this pattern are generally low molecular weight and water soluble. Examples of pattern 2 drugs would be ethanol (molecular weight = 46.07 g/mol), atenolol (molecular weight = 266 g/mol), and some sulfonamides (molecular weights typically <250 g/mol). Pattern 3 distribution evokes very large V_d values because of tissue partitioning, which may or may not be related to the site of action. Highly lipid-soluble compounds that can concentrate into fat tissue also tend to have higher V_d values. Most drugs follow a nonuniform distribution

pattern, also referred to as *pattern 4*, which is a combination of patterns 1–3 [23]. These drugs display different lipid/water solubility and varying abilities to pass through membranes. In some cases, this may result in higher concentrations within sites with higher rates of blood flow such as the kidney and liver, which can be reflective of the amount of drug being excreted. These drugs can have a V_d value within a wide range.

4.4.3 Rate of Blood Flow

The rate of distribution of a drug to organs is dependent on the blood flow rate to these regions. Highly perfused organs such as the heart, liver, lungs, kidneys, and brain reach equilibrium more rapidly because the rate of blood flow is higher. Areas where blood flow is lower such as skin, bone, and fat have a slower rate of equilibration. The rate of blood flow can also differ between rest and exercise and is dependent on physiological cues.

4.4.3.1 Rate of Blood Flow to Organs and Blood Perfusion Rate. Systemic flow is the culmination of flow through many parallel circuits supplying different organs and tissues. Since systemic and pulmonary circulation is one continuous circuit, the flow through the lungs is entirely dependent on the flow through the systemic circulation. Because they are integrated, both the systemic and pulmonary flow must each be equivalent to the volume pumped by each ventricle, which is the cardiac output. Cardiac output is the product of the stroke volume and the number of heartbeats per minute. In a typical 70-kg male volunteer at rest, the average stroke volume of the left ventricle is 0.08 L, while the average heart rate is 69 beats/min; therefore, at rest, cardiac output is about 5.5 L/min [1]. However, due to biological barriers, capillary permeability, and other physiological requirements, the quantity of blood flowing through each organ or region supplied by the systemic circulation is regulated. Table 4.2 outlines the cardiac output to various organs when a healthy, 70-kg man is resting. Cardiac output can increase with exercise or during emotional or physical stress, which can include illness, trauma, or disease. In contrast, if there is a decrease in stroke volume from dehydration or blood loss, there will be a decrease in cardiac output. Therefore, it should be considered that there are ranges to the outputs described in Table 4.2.

TABLE 4.2 Blood Perfusion Rates for Selected Organs

Organ	Perfusion Rate (mL/min/mL of Tissue)	Percentage of Cardiac Output
Skin	0.05	5
Bone	0.02	5
Muscle	0.03	15
Fat	0.01	2
Brain	0.55	15
Heart	0.7	4
Liver	0.75	20
Kidneys	4.5	24

4.4.4 Plasma Protein Binding

Plasma comprises ~55% of the total blood volume and is composed of water containing trace amounts of salts, minerals, and nutrients. Plasma contains a variety of proteins such as immunoglobulin and fibrinogen (for clotting); however, one of its main constituents is albumin, which comprises ~60% of the total plasma protein [24].

Among serum proteins, human serum albumin (HSA) and AGP play important roles in protein binding of many drugs, which is important in determining drug distribution throughout the body [25]. Albumin is basic, and therefore preferentially binds acidic and neutral compounds, while basic drugs can bind to AGP, which is acidic. Since albumin is a good carrier for acidic drugs, many drugs will circulate through the bloodstream bound to it. While drugs can bind to other plasma proteins, such nonspecific binding occurs to a much lesser extent. Binding of drugs to albumin, which enables circulation throughout the body, can also limit distribution to the surrounding tissues, since only the unbound portion is free to enter tissues from the bloodstream [26]. Since protein binding may retain and thereby determine the amount of drug within the central blood compartment, a higher degree of protein binding will produce a lower V_d . It has been shown that some medical conditions that alter the levels or binding properties of plasma proteins can affect the degree of plasma protein binding of drugs, and thus lead to drug interactions [27–29]. For instance, disease and stress can induce conformational changes in plasma or tissue proteins through synthesis of endogenous substances that can interfere with binding. Conjunctive tissue diseases, such as aging, prolonged bleeding, and starvation, are characterized by reduced plasma proteins, while heart infarction or liver morbidities can increase AGP levels, which can change binding profiles of basic drugs and affect distribution or pharmacokinetic and pharmacological parameters [27,28,30]. During pregnancy, albumin levels have been shown to decrease, thereby resulting in notable increases in unbound fractions for diazepam, valproic acid, phenytoin, phenobarbitone, salicylic acid, pethidine, lignocaine, dexamethasone, sulfafurazole, and propranolol [31,32]. A summary of pathological and physiological conditions that can affect protein binding through modulation of HSA, AGP, or lipoprotein levels can be found in Table 4.3 [33]. It is important to note that changes in the unbound drug fraction do not always result in proportional changes in clearance or distribution volume. Important contributors to the extent of concentration change will also be the extent of binding, type of clearance, the size of the distribution volume, administration route, and concomitant changes in intrinsic (cellular) clearance function caused, for example, by induction or inhibition of hepatic enzymes [28].

4.4.5 Red Blood Cell Partitioning

Although not as routinely discussed as plasma protein binding, red blood cell (RBC) partitioning is an important factor for determining V_d and clearance. Establishing the kinetic properties of drug binding to RBC enables appropriate selection of a biological fluid (whole blood, plasma, or serum) for analyzing drug concentration. This ensures more physiologically relevant PK parameters and improves the analytical sensitivity for drugs with K_b/p (whole blood-to-plasma ratio) or K_e/p (drug affinity to binding sites in erythrocytes relative to those in plasma) >2.0 . Chiral characteristics, lipophilicity, and molecular size are all important determinants of RBC partitioning. In some cases, partitioning can occur by passive diffusion (organic, anionic drugs, and nonelectrolytes), through aqueous channels by small hydrophilic compounds (<150 D), or, in

the case of lipophilic compounds, through dissolving into the lipid bilayer membrane. Binding of drug to RBC can occur to hemoglobin and [34] membrane or proteins within the cytosol such as carbonic anhydrase. Additionally, RBCs have the ability to metabolize some drugs, which can add another consideration to the disposition of drugs and the predictions of PK parameters. The rate and extent of RBC binding can

be determined by *in vitro* methodologies where drug is added to suspended RBC in plasma or water containing plasma. Or by *ex vivo* methods where drug is administered to humans, samples are collected and RBC and plasma are separated through centrifugation after which levels of drug are measured in both biological fluids. In some cases, such as with neuroleptic drugs (butaperazine, haloperidol, and thioridazine), the RBC concentration is better correlated with therapeutic effect or dose than plasma concentrations and in the case of digoxin toxicity, RBC concentration better distinguishes between toxic and nontoxic drug levels than plasma concentrations [34].

4.4.6 Perfusion and Diffusion

The distribution of the free fraction of drug can be limited by tissue perfusion rate or by diffusion of the drug across barrier membranes. Only small molecules that are not bound to albumin can undergo diffusion because, when bound to albumin, the molecular weight of the complex is so high (>68,000 kD) that it limits diffusion [35]. However, this protein binding is not a static process and can be described with an on-off rate equation. Passive diffusion occurs when drug moves from an area of high concentration to an area of low concentration following the equation of Fick's law of diffusion [22]:

$$\text{Rate of drug diffusion} = \frac{-DKA(C_p - C_t)}{h}$$

In this equation, C_p is the concentration of drug in plasma, C_t is the concentration of drug in tissue, A is the surface area of the membrane, K is the lipid-water partition coefficient, D is the diffusion constant and is inversely proportional to the weight of the drug, while h is the thickness of the membrane. The negative sign denotes the net transfer of drug from inside the capillary lumen into tissues and extracellular spaces. In this manner, the diffusion is both spontaneous and temperature dependent. In the case of nonpolar, highly lipid-soluble drugs there can be a perfusion rate limitation. Being described as perfusion rate-limited assumes that on entry into blood circulation, the drug is free to distribute completely and instantly across membranes without diffusion barriers. In this case, it is limited only by the rate of blood flow to the organ. If drug distribution is limited by perfusion, the distribution equilibrium may take longer to achieve when perfusion is low and the partition coefficient is high. If the permeability coefficient is high, then the concentration of drug at the tissue must be high before equilibrium takes place. In the case of diffusion rate-limited distribution, as would most likely occur with polar drugs, the rate of distribution into tissue is a function of the permeability coefficient of the drug, the concentration gradient, the distance that the drug travels, the surface area for diffusion, the temperature, and the molecular weight of the drug since smaller lighter molecules will diffuse faster than larger heavier ones. Capillary permeability can also have a profound effect on drug distribution.

4.4.7 Capillary Permeability

The lining of endothelial cells that make up the blood vessels, the lymphatic vessels, and the inside of the heart can affect capillary permeability to drugs depending on how tight the junction between the cells is. The capillary endothelium has discontinuous junctions, which can make the capillary walls quite permeable [36]. For instance,

lipid-soluble drugs can pass through vascular endothelium rapidly, whereas water-soluble drugs will penetrate more slowly, and the rate is dependent on physiochemical properties such as molecular size. Additional physiochemical properties that can affect the rate of transfer across the capillary membrane are whether the drug is ionized and this depends on the pK_a of the drug and the pH of the blood as discussed in Section 4.3.1. Membrane permeability tends to restrict the transfer and distribution of drugs once they are delivered to the tissue. The other major factors that determine the rate of drug distribution is blood perfusion and the expression of transporters.

Two deviations to the typical capillary structure can result in variation from normal drug tissue permeability.

1. The renal and hepatic capillaries in the membrane of the endothelial cells, known as *fenestrations*, are larger, thereby increasing permeability that enables more extensive distribution of many drugs out of the capillary beds of the kidney and liver. Since both these organs serve as sites of elimination, this would serve to reduce the plasma concentration by acting as a mechanism of clearance (refer to Section 4.8).
2. An opposite phenomenon exists within the brain where capillaries seem to have relatively impermeable walls compared with normal vascular endothelium. This greatly restricts the permeability of molecules from blood to brain tissue, despite the cardiac output being relatively high.

The brain capillaries and the renal and hepatic capillaries are two important deviations from the normal capillary wall and both have a profound effect on drug distribution [36]. Capillaries within the brain have tight junctions and have endothelial cells that are so close together that they form the BBB. This limits the distribution of drugs into the brain, and generally only lipid-soluble drugs, or drugs that resemble endogenous substances and are actively transported, can enter the brain. In general, polar or ionized drugs cannot distribute in the CNS. In contrast, the capillary walls in the kidney and liver are very permeable since there are large gaps in the junctions between the endothelial cells and fenestrations through the cell cytoplasm allowing movement of drugs and plasma proteins. This enables rapid and extensive distribution of drugs and proteins out of the capillary bed, which is well suited for these organs since they play such an important role in drug elimination. Since the distribution of a drug to tissues can be dependent on the permeability of the capillaries at the site of distribution, Table 4.4 describes the various pore sizes of some of these barrier membranes. These

TABLE 4.4 Capillary Permeability

Barrier Membrane	Pore Diameter (Å)
Intestinal epithelium	4
Capillary endothelium	40–80
Muscle capillaries	60
Glomerular capillaries	75–100
Glomerular endothelium	1000
Liver capillaries	1000

barriers to distribution are described in more detail in Section 4.4.9. Other capillary beds with tight junctions that can limit distribution include those found in the testicles, eyes, and synovia [36]. Disease states such as inflammation, liver disease, and diabetes can affect capillary barriers and therefore disable or enable entry of drugs and thus change the normal distribution pattern observed in the healthy state [36].

4.4.8 Tissue Storage

As mentioned in Section 4.4.1, some drugs may accumulate in certain types of tissues and act as a reservoir, slowly releasing the drug into the bloodstream, thus keeping the blood level of the drug from decreasing rapidly and prolonging its effect. These drugs generally exhibit pattern 3 distribution, as described in Section 4.4.2, and tend to have very large V_d values. For example, long-term administration of the antimalarial agent quinacrine results in accumulation in the liver [37] and gentamicin binding to tissue results in accumulation in the kidney and vestibular system [38]. This phenomenon can be attributed to binding of drug to cellular constituents such as proteins, phospholipids, or nuclear proteins, as described above. An additional mechanism of accumulation within tissues can be attributed to active transport (e.g., liver enrichment of statins), which is covered in more detail in Section 4.5. Fat can also serve as a reservoir for many lipid-soluble drugs and since the blood flow to adipose tissue is only 2% of cardiac output, it serves as a rather stable reservoir. Drugs that accumulate in fatty tissues can leave the tissue so slowly that the drug can still be present in the bloodstream for days after dosing has ceased. An example of highly lipid-soluble xenobiotics that extensively distribute into fat are polychlorinated biphenyls and dicophane. Other examples of drugs stored in fat would be the lipid-soluble barbiturate thiopental, remifentanyl, and some other β -blockers [39,40].

Bone can also serve as a site of accumulation for drugs such as tetracycline antibiotics, other divalent metal-ion chelating agents, and heavy metals [41]. Drugs and other toxic agents such as lead or radium can accumulate into the bone crystal surface and incorporate into the crystal lattice where effects can persist long after exposure [42]. This type of accumulation and exposure can have therapeutic advantages for treatments aimed at osteoporosis. Bound drug in the bloodstream can also serve as a reservoir since the drug will be released as the unbound levels decrease. As an example, digitoxin and phenytoin can be sequestered by plasma proteins, which then act as a reservoir for drug [43].

4.4.9 Physiological Barriers to Drug Distribution

Epithelial and endothelial cells act as internal barriers, while external barriers include keratinized epithelium (skin), ciliated epithelium (lung), or epithelium with microvilli such as is found in the intestine. These types of cells are connected by zonulae occludens, which is a tight junction that creates an unbroken phospholipid bilayer [44]. There are also internal or blood–tissue barriers that are made up of endothelial cells joined via zonulae occludens [45]. In these cases, drug permeation occurs mostly in the capillary beds, for example, endocrine glands in the gut have fenestrations on endothelial cells, which allow for passage of small molecules, whereas the liver has large fenestrations (~ 100 nm), thereby allowing drugs to exchange freely between the blood and interstitium [45]. Cardiac muscle has high endo- and transcytotic activity,

Figure 4.4 A depiction of xenobiotic transporter expression at the placental barrier where the expression of efflux transporters serves to protect the fetal compartment from exposure to substances that are substrates for the expressed transporters. *Source:* Extracted from Ref. 81. (See color insert.)

which enables drug transport via vesicles, whereas the CNS has endothelia that lack pores and possess only a little transcytotic activity, therefore limiting diffusion to small lipophilic drugs that can undergo transcellular passive diffusion [46]. This provides a barrier that is very restrictive and limits the types of drugs that can permeate.

4.4.9.1 Maternal:Fetal Barrier. The composition of the placental barrier changes over the course of pregnancy, but it consists of the chorion frondosum (fetal tissue) and deciduas basalis (maternal tissue), which are divided into cotyledons separating the maternal and fetal circulation [47]. It is composed of a single layer of polarized epithelial cells known as the trophoblast, which contains the syncytiotrophoblast, and the fetal capillary endothelia (refer to Fig. 4.4). Drug flux can occur across the apical (toward maternal) and basolateral (toward fetal) membranes of the syncytiotrophoblast [47]. The placenta is very well perfused and therefore not as impenetrable as often thought [48]; while most lipophilic drugs can readily cross by diffusion, there are a large number of efflux transporters present, similar to those expressed in the brain, allowing export of drugs out of the placenta. Uptake transporters are also present [49], which facilitate the transport of more hydrophilic nutrients. Although these mechanisms are covered in more detail in Section 4.5, it is important to note that the presence of efflux transporters can limit intracellular concentrations and hence exposure to the fetus, despite the ability of lipophilic drugs to readily diffuse. The physiochemical properties of the drug and whether it is a substrate for transport processes have a large impact on the actual fetal exposure. Physiological and physiochemical factors previously covered such as lipid solubility, extent of plasma binding, and degree of ionization of weak acids and bases are also important general determinants in drug transfer across the placenta.

4.4.9.2 Mammary Gland. The mammary gland represents an important barrier that limits drug exposure to a suckling infant. The functional unit for milk production and the milk–blood barrier is a single layer of epithelial cells in the alveoli, which are extensively proliferating during lactation [50]. The mammary gland is highly perfused

with a large surface area, and therefore distribution of drug to milk is generally similar to that of blood with very little lag time. However, there is high expression of transporters that can serve to limit the extent of exposure to drug. Additional factors that may influence drug distribution include the slightly lower pH of milk (7.2) compared with blood, thereby allowing ion trapping of weak bases [51]. There can also be a degree of binding to milk proteins and, since the milk fat content is high, lipophilic drugs may have large milk to serum concentration ratios due to partitioning into milk [52]. There is also evidence of transporter expression on the mammary epithelium, mostly for endogenous substrate transfer. While there is more extensive discussion of transporters in Section 4.5, it is worth noting that some members of the organic anion-transporting polypeptide (OATP) and multidrug resistance protein (MRP) families have been detected, while ABCB1 (MDR1) and ABCG2 (breast cancer resistance protein (BCRP)) have also been shown to play a role in drug accumulation in secreted milk [53,54].

4.4.9.3 Blood–Brain Barrier. The BBB serves to protect the brain from the contents of the CSF and blood, and it comprises a layer of endothelial cells sealed by tight junctions supported in terms of nutrition and communication by astrocytes [55]. Projections from astrocytes form a communication link between the capillary endothelium and the neurons of the brain, and lipids within the astrocyte cell walls and the tight junctions between the adjacent endothelial cells limit the passage of water-soluble molecules at the BBB. This is not totally impenetrable but slows the rate at which drugs can cross into brain tissue, while still allowing essential nutrients such as oxygen to pass through [56]. The expression of transporters at the apical membrane of the epithelial cells can also prevent distribution of drugs across the barrier and contribute to drug resistance phenotypes [57,58]. As discussed in Section 4.4.3, the rate of blood flow to the brain is quite high, since the percentage of the cardiac output distributed to the brain is around 15%. This enables some highly lipid-soluble drugs, such as certain anesthetics, and small lipophilic compounds, such as barbiturates and benzodiazepines, to diffuse rapidly into the CNS. The role of efflux transporters on the apical membrane can effectively serve to actively exclude a large variety of lipophilic drugs from the brain capillary endothelial cells, thereby limiting the distribution of these types of drugs. This can be beneficial in reducing adverse neurotoxic effects and may also reduce the treatment options for neurological disorders. Therefore, there may be therapeutic advantages to transporter modulation as a mechanism for distribution of novel therapeutics. In contrast to the BBB, the choroid plexus contains fenestrated endothelium, which allows for drug distribution across the choroid plexus [59,60]. The choroid plexus is a continuous layer of epithelial cells that function to control CSF homeostasis. CSF flows from the ventricles across the surfaces of the brain and spinal cord into the venous blood sinuses [61]. The CSF–blood barrier (Fig. 4.5) is composed of choroidal epithelial cells joined together by tight junctions at their apical surface. In this manner, the barrier prevents all but the most lipid-soluble drugs from entering the CSF [57]. This can result in profound differences in concentration of drug between the aqueous CSF and the CNS tissue [62–64]. Similar to the other barriers discussed, there is a large expression of various uptake and efflux transporters, including SLC22A8 (Oat3), SLC16A1 (MCT-1), SLCO1A2 (OATP1A2), ABCB1 [P-glycoprotein (Pgp)], ABCC4 (MRP4), ABCC1 (MRP1), and ABCG2 (BCRP), which profoundly affect drug distribution into the CNS and these are discussed in further detail in the following section [65].

Figure 4.5 A depiction of xenobiotic transporter expression at the blood–brain barrier (BBB) and choroid plexus, cerebral spinal fluid (CSF)–blood barrier. As evidenced in detail above, the expression of efflux transporters is pronounced along the apical membrane of the BBB, thus limiting the exposure of substrates for these transporters into the brain. *Source:* Extracted from Ref. 64. (See color insert.)

4.5 THE ROLE OF TRANSPORTERS IN DRUG DISTRIBUTION

It has become increasingly recognized that most drugs are distributed across cellular membranes with the assistance of transporter proteins. These transporters have been identified in every living cell in varying amounts and are distributed differentially throughout tissues and barrier membranes [66–70]. It is thought that transporters may play an important role not only in distributing drug molecules to their effector site but also in distribution to almost every organ and tissue in the body [66]. This has been shown to contribute to both pharmacological and toxicological effects and to nonlinear pharmacokinetics.

4.5.1 Transporter Subtypes Involved in Distribution

Since the discovery of Pgp as an important contributor to efflux drug transport across membranes and its underlying role in multidrug resistance (MDR) [71], it has become more commonly accepted that transporters can have a large impact in drug disposition. The identification of various transporters has resulted in classification systems based on the method and direction of transport. Transporters that have been identified as requiring the direct binding and hydrolysis of ATP have been grouped into a superfamily of ABC (ATP-binding cassette) transporters. So far, there are at least 49 members of the ABC superfamily identified in humans and these are grouped into seven families and contain therapeutically important and well-studied transporters such as ABCB1, ABCC1, ABCC2, and ABCG2 [72]. Another important large family of transporters is the SLC (solute carrier) transporters of which there are as many as 50–55 gene families

and at least 362 members [73,74]. Included in this class are all the major classes of uptake transporters, including the OATPs and organic cation transporter (OCTs), which have both been implicated in drug–drug interactions [68]. Unlike the ABC transporters, the SLC transporters do not directly utilize an energy source [66]. Together the ABC and SLC transporters are increasingly being implicated in regulation of the passage of endogenous and exogenous chemicals across cellular and tissue membranes, thereby playing a pivotal role in drug distribution and subsequent disposition, efficacy, and toxicity [66]. An additional consideration in understanding the differential distribution of drugs through body compartments within a human population is the occurrence of single-nucleotide polymorphisms within the transporter molecules [75–77]. Since transporters clearly play an important role in drug distribution having an understanding of whether a drug of interest is a substrate/inhibitor of specific transporters can provide a more lucid interpretation of V_d and result in more predictive physiologically based pharmacokinetic (PBPK) modeling (refer Section 4.8.4). This field is rapidly evolving and expanding, therefore while a vast number of transporters have been identified and their respective tissue distribution has been described, it is understood that not all these transporters may result in clinically relevant drug–drug interactions. In 2007, an international transporter consortium was established, and in 2010, a review article was published recognizing the importance of transporters in drug disposition and making recommendations regarding the conduct of transporter studies and data analysis [78].

4.5.1.1 ABC Transporters. ABC transporters make up the largest class of membrane-bound proteins in biology and function by enabling active transfer of molecules across biological membranes, through binding and hydrolysis of ATP [66]. As stated earlier, there are currently at least 49 members within seven families (ABCA–ABCG), which are identified by the presence of a characteristic amino acid motif within the nucleotide binding domains (LSGGQ) [79]. A number of ABC transporters have been shown to be expressed at barrier membranes and are therefore considered important to drug distribution. Table 4.5 summarizes the expression of the ABC transporter mRNA in multiple tissue types in descending order of expression, while Table 4.6 summarizes the gene identification and the alias of the transporters that are involved in xenobiotic transport.

4.5.1.2 SLC Transporters. SLC transporters represent a basic and abundant mechanism by which endogenous and exogenous molecules are distributed across membranes [66]. SLC transporters do not directly access an energy source and they are able to function as uniporters (facilitated diffusion of substrates across membranes), symporters (transport of two compounds in the same direction at the same time), and antiporters (transport of two compounds in opposite directions at the same time) [66,68]. While the majority of the SLC transporters serve to facilitate transfer of highly specific endogenous substrates, a number of them can contribute to MDR and limit accumulation by transporting drugs into and out of cells [68]. As an example, multiple statin drugs are substrates for OATPs that are highly expressed in the basolateral membrane of hepatocytes and this contributes to their ability to accumulate into the liver [75]. Certain SLC transporters can function bidirectionally depending on substrate concentration gradients so they can play the role of efflux transporter. Many OCTs can function in this manner [68]. Often times the extent and direction of drug movement into organs, including the intestine and liver, is determined by the unique interplay between apically and

basolaterally expressed transporters. In this manner, transporters that result in vectorial drug transfer into the systemic circulation are referenced as *absorptive transporters*, whether they are efflux or uptake transporters. Transporters involved in the excretion of substrates from circulation are known as *secretory transporters*. Expression of these transporters on the canalicular membrane of hepatocytes further effects the disposition of drugs since substrates can be effectively eliminated from distribution through hepatic phase I and II biotransformation and subsequent efflux into bile. Table 4.7 summarizes the expression of the SLC transporter mRNA in multiple tissue types in descending order of expression, while Table 4.8 summarizes the gene identification and the alias of the transporters that are involved in xenobiotic transport.

4.5.2 Transporter Expression at Barrier Membranes

The expression of multiple ABC and SLC transporters in the apical and basolateral sides of epithelial and endothelial cells lining pharmacological barriers indicates their importance in protection and detoxification [70]. ABCB1 (PGP) is highly expressed in most barrier tissues, such as the BBB, testis, placenta, and endothelial cells of human cardiac vasculature. Additional transporters of importance include the ABCC family, which consists of the MRPs and ABCG2 (BCRP) and are also expressed in many of the epithelia and endothelia that constitute important barrier membranes. Transporter expression at some important barriers to distribution is shown in Figs. 4.4 and 4.5, which describe transporter location at the BBB and CSF–blood barrier and at the placental barrier, respectively. A number of transporters are also expressed at the blood–testis barrier where tight junctions between sertoli cells allow polarization and barrier formation, which protect the germ cells. These transporters include Pgp, GLUT1, 2, and 3, urea transporter, and potentially OCT1, 3, OCTN1, and 2. The latter are thought to contribute to accumulation of propranolol and imipramine in the testis [81], which may result in adverse effects in this tissue. Additionally, the role of transporters on the apparent V_d should be considered, since transporter-mediated uptake into hepatocytes can affect the extent of clearance and therefore the apparent V_d . An example of this would be cerivastatin, which is highly distributed to the liver both through uptake processes and cellular binding. This has been shown as a mechanism for drug–drug interaction between cerivastatin and CsA, since CsA acts as an inhibitor of cerivastatin uptake.

4.6 IN VITRO METHODOLOGIES FOR DETERMINING DRUG DISTRIBUTION

Some of the different parameters of drug distribution can be determined using *in vitro* methodologies. Well-established methods for evaluating plasma protein binding and determining the role of transporters as well as more recently reported methods are discussed in the following sections. A more detailed description of the transporters involved in drug distribution is given in Section 4.5.

4.6.1 Plasma Protein Binding

Plasma protein binding studies play an important role in the process of candidate drug selection and development. The amount of drug that binds to protein is dependent on

TABLE 4.7 SLC Transporter Expression in Various Tissues^a

Tissue	Expression of the 10 Most Abundant Human SLC Transporters in Various Tissues Ranked from Highest to Lowest									
Adrenal gland	SLC16A9	SLC40A1	SLC25A3	SLC25A37	SLC39A9	SLC24A6	SLC3A2	SLC30A1	SLC6A6	SLC25A44

the concentration of protein, the concentration of free drug, and the drug's affinity for the binding sites of the protein molecule. Plasma protein binding studies allow the determination of the amount of unbound (free) drug concentrations in the blood. A low fraction unbound (f_u) value (e.g., $f_u < 0.1$) indicates that a compound is highly bound to plasma proteins. Plasma protein binding data should be considered with other *in vitro* data to determine the potential of a drug for efficacy in a clinical context. Low protein binding may be more favorable than high protein binding. However, factors such as solubility of the drug and nonspecific binding need to be considered when interpreting data.

These are basic concepts that are important to the understanding of the overall topic of drug distribution.

There are numerous *in vitro* methods for the determination of protein binding, including equilibrium dialysis, dynamic dialysis, ultrafiltration, ultracentrifugation, exclusion chromatography, and circular dichroism [82]. The three most widely used *in vitro* protein binding techniques in pharmaceutical research are those which allow high throughput, namely chromatographic separation, 96-well ultrafiltration, and 96-well equilibrium dialysis [83]. These are discussed further herein. The method of chromatographic separation, for example, using a HSA-immobilized column, separates multiple test compounds on the same column. This allows relative ranking by calculation of percent binding for each compound. This method is easy to set up and use and is relatively inexpensive. With the 96-well ultrafiltration method (an automated and rapid method for analyzing multiple compounds), percent binding is calculated. However, nonspecific binding of the analyte to the plastic housing or ultrafiltration membrane surface can affect the quality of the data. Nevertheless, it is frequently used in industry. The 96-well equilibrium dialysis method is the "gold standard" means of protein binding analysis [83]. Protein binding studies are traditionally performed with ^{14}C -labeled compounds. With the equilibrium dialysis method, the procedure is performed in a 96-well system. There is a membrane in each of the 96 wells with buffer solution added to one side of the membrane and an equal volume of plasma containing the test compound added to the other side of the membrane. The plate is incubated at 37°C with rotation for up to 24 h to allow the incubations to reach equilibrium. The long equilibration times sometimes required could be an issue if the analyte is not stable in plasma under these incubation conditions. Samples are removed from either side of the membrane for analysis by LC/MS/MS. The equation to calculate free fraction is as follows:

$$f_u = \frac{C_{\text{buffer}}}{C_{\text{plasma}}}$$

where C_{buffer} is the unbound compound concentration in buffer after dialysis, and C_{plasma} is the postdialysis plasma concentration [83]. This equation assumes that error added as a result of volume shift is negligible since potential error in the 96-well format is minimized.

The percentages of drug unbound (free) and bound to protein are calculated as follows [83]:

$$\% \text{Free} = f_u \times 100\% \text{bound} = (1 - f_u) \times 100$$

Recovery of test compound at the end of the study should theoretically be 100%. Any deviation from 100% may indicate binding of the compound to the dialysis equipment

or it could also indicate a solubility issue with the compound:

$$\text{Percentage recovery} = \frac{(\text{Buffer compartment [After dialysis]} + \text{Plasma compartment concentration [After dialysis]})}{(\text{Initial solution concentration [Buffer]} + \text{Initial solution concentration [Plasma]})} \times 100$$

Both plasma protein and RBC binding studies are conducted as a routine part of the ADME process. There are many representative examples of routine protein binding studies demonstrating both high and low binding compounds. However, one interesting example is the plasma protein binding studies conducted with radiolabeled dihydroartemisinin in rat and human plasma [84]. Dihydroartemisinin exhibits high binding capacity with both rat and human plasma proteins (76–82%). The concentration of total radioactivity in the plasma fraction is <25% of that in whole blood with total radioactivity distributed in RBCs about three- to fourfold higher than that in plasma, suggesting that the antimalarial potency of dihydroartemisinin (DHA) in treatment of blood stage malaria may relate to the high RBC binding.

4.6.2 Transporter Studies

Transporters and methods to investigate the role of transporters in the body has been discussed more extensively in the chapter titled *Solute Carrier (SLC) Family Transporters*. The objectives and strategies for conducting these types of studies will be related to their impact on drug development. The current methods for investigating protein binding, V_d , and other parameters are described in brief in the following sections.

4.6.2.1 Membrane-Based Assay Systems. There are several established *in vitro* methods to evaluate the role of efflux transporters in the distribution of a drug. The most simple of these methods is the use of “inside out” membranes and vesicles such as those from baculovirus-transfected Sf9 insect cells, which have been engineered to overexpress the efflux ABC transporters specifically. Substrates of the transporter are taken up into the vesicles in an ATP-dependent manner. The two main assays are the vesicular transport assay and the ATPase assay. The vesicular transport assay is a direct measure of transporter activity. Following incubation, vesicles can be separated from the incubation solution by rapid filtration through filters or nitrocellulose membranes. The test compound, trapped inside the vesicles, is retained on the filter. The amount of the transported molecule is determined by quantitative measurement with high performance liquid chromatography (HPLC), LC/MS/MS, radioactivity, or fluorescence measurement. This method is not suitable for lipophilic or adsorptive drugs; however, it can be used for “nonsticky” transporters regardless of basal ATPase activity. As an alternative assay method, ABC transporter membranes that are dependent on hydrolysis of ATP can be used with an ATPase assay to determine possible substrate or inhibitor properties of test compounds. The ATPase assay is an indirect measure of transporter activity. ATP hydrolysis yields inorganic phosphate, which can be measured by a simple colorimetric reaction. The amount of inorganic phosphate is directly proportional to the activity of the transporter. This assay system is simple to use and can be used in a high throughput manner. It is suitable for lipophilic drugs but not appropriate for use with transporters of high basal ATP activity such as MRP4, MRP8, bile salt export

pump (BSEP), and BCRP. This assay requires less transporter protein than the vesicle transport assay; however, high concentrations of compound are required.

The advantages of using membranes and vesicles are the simplicity of the system and the focus on a single transporter. When testing hydrophobic compounds, there can be a high degree of background binding of the compound to cell membranes in vesicle or cellular systems. However, these assays when used with other *in vitro* methods help the investigator to understand, more thoroughly, the relevant PK properties of new drugs.

4.6.2.2 Cell-Based Assay Systems. Cell-based transporter assays can determine if a test compound is a substrate or inhibitor of an individual transporter. Whole cell models have an advantage over membrane and vesicle assays as they can be utilized to study both uptake and efflux of test compounds. These systems can thus be used in studies to determine transport mechanisms. Bidirectional transport, namely apical-to-basolateral and basolateral-to-apical flux, can be measured to determine the transport of a test compound across the small intestine (Caco-2 cell line) or BBB. Caco-2 cells endogenously express numerous uptake transporters, which can make identifying uptake transporter substrates in these cells difficult. As an alternative approach, cell lines such as the epithelial cell line, Madin-Darby canine kidney (MDCK), can be specifically transfected to express recombinant uptake, efflux, or both transporters. For example, MDCK cells transfected with the MDR1 gene (MDCK-MDR1) express the efflux transporter, human Pgp. The MDCK-MDR1 cell line has superior transepithelial electrical resistance (TEER) values compared with Caco-2 and wild-type MDCK cells. Higher TEER creates a very tight cell system that allows for increased sensitivity in identifying Pgp substrates. Therefore, a transporter effect observed in the MDCK-MDR1 cell system may not necessarily be observed in the Caco-2 cell system. The lower TEER values of the Caco-2 cells create a more “leaky” system, which may be more representative of the human small intestine. Use of transfected cell lines such as MDCK-MDR1 allows focus on a single transporter and could help identify drug permeability issues early on in drug development.

Cells isolated from intact tissue (primary cells), such as hepatocytes isolated from liver tissue, can also be used to evaluate ADME properties of a compound, including the role of transporters in distribution. Primary cells are more difficult to maintain in culture than cell lines. In the case of hepatocytes, the sandwich culture method was developed to help maintain more *in vivo*-like properties such as cell polarity and shape and bile canaliculi reformation. One disadvantage of the cell culture systems is the static nature of the culture without “flow” properties. The different primary hepatocyte cell models such as suspension, monolayer, and sandwich culture formats are discussed in more detail in the chapter titled *Solute Carrier (SLC) Family Transporters*.

4.6.3 *In Vitro* Methods to Study the Brain Tissue Distribution

In vitro models of the brain have been developed for estimating unbound drug concentrations in the brain interstitial and intracellular fluids [85]. The method uses brain slices from rat and guinea pig for uptake studies and brain homogenate for binding studies. Agreement between *in vivo* and *in vitro* methods for estimating the unbound brain volume of distribution ($V_{u, \text{brain}}$) has been established by comparing *in vitro* data with microdialysis data *in vivo*. Microdialysis is discussed in more detail in Section 4.7.2.1.

The brain slice method is suitable for measuring tissue distribution of hydrophilic through to very lipophilic compounds in a high throughput manner [86] and measures the partitioning of drug between buffer and brain slice to yield, $V_{u, \text{brain}}$. The unbound drug concentration in the brain interstitial fluid, the most relevant measure of central drug exposure, can then be calculated from the measured total amount of drug in brain tissue using $V_{u, \text{brain}}$ as a conversion factor. Friden and colleagues have optimized their method and combined the use of brain slice and brain homogenate studies to define the intracellular to extracellular partitioning of unbound drug in the brain tissue [86,87]. Models to assess drug distribution in the BBB have been reviewed by Alavijeh *et al.* [82]. With respect to *in vitro* cell models of drug distribution in the brain, MDCK cells are considered a good predictor of BBB permeability as they have a high trans-membrane resistance causing tight junction between the cells, as exists in the BBB. Assessment of passive diffusion across the BBB and Pgp transport can also be studied with MDCK cells. The combination of the two parameters allows BBB permeation and active efflux out of the BBB to be modeled. However, the endothelial cells such as Caco-2 express a greater range of transporter molecules, which makes them much better suited for studies investigating different transporters within the BBB. *In vitro* methods assessing transport function in the liver and kidneys is discussed in the chapter titled *Solute Carrier (SLC) Family Transporters*.

4.7 IN VIVO METHODOLOGIES FOR DETERMINING DRUG DISTRIBUTION

Drug distribution can be difficult to determine *in vivo*, particularly in man where whole tissues or organs cannot be analyzed directly. Traditional methods, in addition to modern methods such as imaging and analysis, are discussed in the following sections. Many of these current techniques have been used in both animal and human studies. Most current tissue distribution studies consist of a combination of both traditional and modern methods.

4.7.1 *In Vivo* Studies in Preclinical Animals and *Ex Vivo* Organs

Drug distribution studies have been performed in preclinical species by collection and analysis of organs and techniques such as whole body autoradiography (WBA). Generally, a study would involve single oral or intravenous doses of increasing concentrations of radiolabeled drug being given to a preclinical species such as rat. Blood samples would be taken at time intervals from animals for pharmacokinetic analyses. For tissue distribution analysis, animals are euthanized at each time point and tissue and organ samples taken. Aqueous homogenates are prepared from most tissues and radioactivity measured in each. Feces and urine are collected from animals housed in metabolism cages and analyzed. Furthermore, blood, fat, the contents of the stomach, and contents of different sections of the intestine are also collected and analyzed. For example, radiolabeled dihydroartemisinin, a powerful antimalarial drug has been studied in rats [84] to determine pharmacokinetics, tissue distribution, and mass balance. Tissue distribution study methods are described in detail in the study by Xie *et al.* [84]. WBA is a drug distribution process using radiolabeled drug in live animals such as rat. It is a sensitive and quantitative method. The main advantage of WBA is that it

allows collection of maps of the spatial and temporal distribution of a drug in individual tissues and throughout the body. However, it is not possible to distinguish whether the radioactivity detected is from the drug or from its metabolites. Furthermore, it is limited in the identification of the distribution of more than one compound administered simultaneously. It is an invasive technique and analysis is postmortem, therefore a large number of animals are required.

In pharmacokinetic studies conducted in preclinical animals or in humans, the most common procedure is where a mixture of known amounts of labeled and nonlabeled drug are administered in experiments to evaluate the mass balance and tissue distribution of the drug. The total dose used in the radiolabel studies is usually a pharmacologically relevant dose. This dose can be determined from results of early efficacy studies. If a specific dose has not yet been established, a total dose of radioactivity could be 100 μCi , or less, providing that exposure of a specific tissue to the radiolabeled drug does not exceed radiation limits to avoid local radiation damage [87]. The most commonly used radioisotope is ^{14}C . It is highly stable and therefore no radiolytic or chemical decomposition of the compound occurs. Disadvantages of using radiolabeled compounds include the obvious potential health risk of radioactivity exposure to humans, the expense to synthesize and purify the radiolabeled compound, the time required for this process, and the further expense of correct handling and disposal of radioactive material.

There are also *ex vivo* and other *in vivo* models to study drug transport and V_d . *In vivo* models such as gene-knockout and transporter-deficient animal models are now used in drug distribution studies. Transporter knockout models can be used to establish the extent of the importance of the pathway removed by the knockout process to the overall clearance of a drug. In these knockout models, compensatory mechanisms may come into play by upregulation of other pathways involving alternative transporters and metabolizing enzymes, and this will complicate interpretation of results. Factors such as sex, species, strain, housing conditions, and diet can affect the outcome of these studies and also need to be considered when interpreting results and in cross-species comparisons [78].

There is particular importance in studying transporters in drug distribution not only due to the potential inhibition of a transporter by a comedication but also because of the genetic polymorphisms of transporters in the human population. Recently, matrix-assisted laser desorption ionization (MALDI) imaging mass spectrometry coupled with high definition histology has been used to follow the *in vivo* transport of unlabeled drugs within specific organ and tissue compartments [88]. The authors tracked and quantified the distribution of an inhaled reference compound, tiotropium, a bronchodilator used in the treatment of chronic obstructive pulmonary disease (COPD), within the lungs of dosed rats. Drug ion distribution patterns compared between adjacent tissue sections, showing tiotropium parent MS ions and fragmented daughter MS/MS ions, were dispersed into the lung and pleura, in a concentration gradient. For comparison, levels of drug measured in the lung compartments by a chemical extraction method were similar. Change in volume of distribution for any reason, such as a disease process, aging or genetic polymorphisms in transporter genes, for example, can lead to a significant change in drug efficacy or likelihood of toxicity, as well as a change in its half-life independent of a change in clearance. Comparing studies reported in the literature, Grover and Benet [89] concluded that the liver is a larger contributor to distribution volume than the kidneys, taking into consideration both uptake and efflux transporters.

4.7.2 Studies in Man

Classical methods for pharmacokinetic measurements were the major option to determine tissue distribution of a test compound in patients. In these studies, plasma levels of parent drug and metabolites are commonly determined following intravenous administration of a drug by infusion over time. For example, Fogli *et al.* [90] administered paclitaxel followed by gemcitabine to patients with non-small-cell lung cancer and were able to determine volume of distribution as well as other pharmacokinetic parameters to optimize their treatment regimens in phase I trials. In another interesting ADME study, the adipose tissue and plasma distribution of various antiretrovirals in HIV-1-infected patients was investigated [91]. Plasma samples were collected in a routine manner. Adipocyte samples were collected, as a by-product of liposuction plastic surgery in patients suffering from lipodystrophy. Protease inhibitor (PI) and nonnucleoside reverse transcriptase inhibitor (NNRTI) concentrations in plasma and adipocyte lysates were determined by HPLC assays coupled with either ultraviolet photodiode array or spectrofluorimetric detection. The concentrations of these compounds in adipocyte lysates indicated that in patients with effective nadir plasma concentrations of PI and NNRTI, PIs may diffuse into fat tissue. The authors concluded that NNRTIs have a high affinity for fat tissue and may accumulate there.

4.7.2.1 Microdialysis. The technique of *in vivo* microdialysis has become one of the major tools to sample endogenous and exogenous substances in extracellular spaces [92]. Microdialysis is a semi-invasive technique based on the passive diffusion of substances across a small semihollow fiber permeable membrane (a probe), connected to an inlet and outlet tubing with a small diameter to allow the interior of the probe to be perfused with a suitable carrier solution [93]. Although developed for use with intracerebral measurements, it is now used to measure drug disposition in many different tissues, organs, and biological fluids. One advantage is that the samples taken are generally stable due to the absence of enzymes in the sample. Therefore, samples can be analyzed after the procedure. Samples are commonly separated using liquid chromatography or capillary electrophoresis to isolate the drug and/or drug and its metabolites from endogenous compounds. Detection is usually by fluorescence, electrochemical, or mass spectrometry [93]. This method allows continuous monitoring of drug or metabolite concentrations over significant time periods. Extracellular concentration gradients caused by transport of the drug or perfusion differences can also be evaluated. Compared with other techniques, microdialysis does not cause fluid loss or pressure in the tissue being measured since the samples are replaced by fresh fluid. Cells, protein, and debris are excluded from the dialysate by the semipermeable membrane. This helps prevent enzyme degradation of the sample and maintains clean samples that can be analyzed without the need for a clean-up step.

The microdialysis technique was reviewed by Zhou and Gallo [92] and they discussed many examples where microdialysis has been used to measure tumor-specific drug concentrations compared with plasma drug concentrations, as an indicator of tumor response to chemotherapy. Microdialysis has also been used to measure the unbound drug concentration in biological fluids. This permits direct measurement of plasma protein binding *in vivo* [94]. Disadvantages include local damage to the tissue, circulation, and membrane barrier integrity. It has lower spatial and temporal resolution compared with some other techniques. If low flow rates are used in the experiment,

this technique may not be suitable for use with lipophilic compounds as they may stick to the probe.

4.7.2.2 Positron Emission Tomography. PET is a noninvasive technique that involves the patient being injected with a biologically active, radiolabeled drug (radiotracer) that localizes at targeted sites within the body. Radiation emitted from the site or sites of accumulation is detected by a bank of detectors to produce a three-dimensional image of the radiotracer of drug distribution. A positron-emitting radionuclide is used as the label in PET [95]. PET methods are very sensitive and allow determination of absolute radioactivity concentrations within tissues [96]. Rosso and coworkers [97] characterized the distribution of temozolomide, an important alkylating agent used in the treatment of brain tumors. These studies predicted normal brain and brain tumor temozolomide concentration profiles for different temozolomide dosing regimens allowing optimization of treatment schedules.

4.7.2.3 Magnetic Resonance Techniques. Two other imaging methods to measure drug disposition *in vivo* noninvasively are MRI and magnetic resonance spectroscopy (MRS).

MRI can be thought of most simply as the measuring and mapping of the magnetic properties of an object. Instead of measuring the magnetism point to point in the object, MRI can create an image that depends on the rates of magnetization for each point [95]. MRS produces spectra that depict individual changes in the concentrations of parent drug and metabolite for a sensitive volume. However, there is no simple means with MRS to measure absolute concentrations [96]. Compared with PET, MRS imaging has low spatial resolution and average drug concentrations are usually obtained from large regions of interest (e.g., whole brain).

Human blood-oxygenation-level-dependent (BOLD) functional magnetic resonance imaging (fMRI) is based on the fact that changes in the oxygen level in the blood can affect the fraction of hemoglobin in the deoxygenated state. This can be used to create image contrast [98], and the technique has been used to investigate how anxiolytics such as benzodiazepines affect amygdala functioning in healthy volunteers [99]. This technique is relatively novel and its range of applications is still being established.

4.7.2.4 Modeling. PBPK models are also used to predict ADME, including drug distribution. Some of these are discussed in detail in the study by Theil *et al.* [100] and mentioned elsewhere in this chapter. Mathematical models to reflect different aspects of drug distribution are described in the literature. Examples are models for plasma protein binding and how it affects rates of uptake of drugs to the brain [101] and models to predict the distribution of drugs delivered intracranially to the brain [111].

4.8 CALCULATING DISTRIBUTION

The relationship between the concentrations of a drug found in the different parts of the body with time after administration of a dose is known as *pharmacokinetics*, and an understanding of pharmacokinetics is crucial to enable both optimal and safe use of drugs in patients and new product development. Pharmacokinetic data are obtained by

Figure 4.6 One-compartment model with a well-perfused central compartment.

measuring the concentration of drug in various tissues and body fluids over a period of time and fitting them to a mathematical model of the body.

4.8.1 One-Compartment Model

Although the movement of drug between the compartments of the body is a complex dynamic process, a simple analysis can be made by assuming that all the body compartments are in rapid equilibrium with a central compartment, which is usually interpreted as the blood, and that the concentration of a drug is constant throughout this compartment (Fig. 4.6). In this simple model, the body is considered to be a single well-stirred compartment, and it is assumed that if a drug is injected (e.g., intravenous injection) into this compartment, it will instantaneously distribute throughout it. Thus, the concentration of drug at zero time (C_0) can be calculated, and if C_0 is known, then V_d , the volume of distribution, can be calculated:

$$C_0 = \frac{D}{V_d}$$

where V_d is the volume of distribution and D the dose.

V_d does not represent the volume of an anatomical compartment, but links the total amount of drug in the body to its concentration in blood plasma. As described in Section 4.4.1, total body water is divided into the plasma water, the interstitial water, the blood cell/transcellular fluid, and the intracellular water, and the way in which a drug distributes between these will affect its plasma concentration. If the drug only distributes into plasma water (about 3 L in man), then its plasma concentration will be higher than if it distributed into all the extracellular water (about 14 L) or indeed total body water (about 40 L).

Although the V_d is a mathematical parameter, without absolute physiological meaning, it gives important information about a compound. A very high V_d value indicates that the drug is localized or sequestered in a storage site such as fat or bone. On the other hand, if the V_d is low, then it indicates that the drug is retained in the plasma (an example of various drugs and their corresponding V_d can be found in Table 4.9).

Clearance of the drug from the central compartment takes place at a rate determined by the elimination rate constant, K_{el} , which represents removal of drug by all processes from the biological system. For many drugs, a plot of log drug concentration versus time yields a straight line and indicates first-order kinetics where the rate of elimination is proportional to the drug concentration (Fig. 4.7). This means that the time taken for the plasma concentration of drug to halve will always be the same regardless of where on the curve the original value is taken. This time is referred to as the *half-life* of

TABLE 4.9 Values of Volume of Distribution for Selected Drugs

Drug	V_{ss} (L)
Humira (mAb)	5
Warfarin	8
Gentamicin	15
Phenytoin	50
Cyclosporine	300
Digoxin	400
Desipramine	3000
Quinacrine	40,000

**Figure 4.7** Theoretical log plasma drug concentration versus time curve for a one-compartment model.

the drug ($t_{1/2}$). The elimination rate constant is inversely related to the half-life of the drug:

$$K_{el} = \frac{0.693}{t_{1/2}}$$

The faster the clearance of the drug, the faster one half of the concentration of the drug will be cleared and the shorter will be the half-life. If the pathways of elimination of a drug are saturated (e.g., a cofactor may become rate limiting), then the elimination rate becomes independent of drug concentration, and the drug is being cleared as fast as possible. This is seen with the metabolism of acetylsalicylic acid [102] where the conjugation pathways are saturable and with ethanol metabolism where the cofactor, nicotinamide adenine dinucleotide (NAD), is the rate-limiting factor.

4.8.2 Two-Compartment Model

The simple single-compartment model assumes that the rates of absorption, metabolism, and excretion are all directly proportional to the concentration of drug in the compartment from which the transfer is occurring. However, the different organs of the body,

Figure 4.8 The two-compartment model with a central and peripheral compartment.

Figure 4.9 Theoretical log plasma drug concentration versus time curve for the two-compartment model.

for example, the brain, body fat, and muscle tissue, are very different in terms of their blood supply, permeability of their capillaries to drugs, and the partition coefficient for drugs, and all these differences affect the time course of drug distribution. A two-compartment model, which introduces a separate peripheral compartment to represent the tissues, in contact with the central blood compartment, resembles the real body situation more closely (Fig. 4.8). In this case, the plot of log drug concentration (in the central compartment, i.e., in the blood) shows two distinct slopes (Fig. 4.9). The first steeper slope represents the distribution of the drug from the blood to the tissues, which results in a rapid fall in the blood concentration, and the second slower phase is the elimination of the drug from the central compartment. The half-life for the slow phase provides an estimate of the K_{el} . If a drug is rapidly metabolized, then the two phases are not well separated.

The mathematical analysis of a two-compartment model is more complex than a one-compartment model, and in practical terms, drugs are not usually given intravenously. Where a drug is administered by a route other than intravenously, the plasma concentration profile will be a composite of absorption in addition to distribution and elimination. For a one-compartment model, the absorption rate constant (K_a) and the elimination rate constant K_{el} can be calculated by extrapolation of the appropriate part of the log dose curve (Fig. 4.10), but in the two-compartment model, absorption, distribution,

Figure 4.10 Theoretical log plasma drug concentration versus time curve for a one-compartment model with an initial absorption phase.

and elimination are occurring simultaneously and the curve is difficult to analyze satisfactorily. Pharmacokinetic data from orally administered drugs are also difficult to analyze. The administered dose of the drug may not be the same as the dose which is absorbed and available systemically. This is due partly to incomplete absorption from the GI tract and to first-pass metabolism mainly by the liver. The extent of first-pass metabolism by the liver can be extensive. For example, approximately 70% of the drug propranolol is metabolized before it reaches the systemic circulation when given orally [103]. The dose of a drug actually absorbed can be quantified by measuring the area under the plasma concentration versus time curve (AUC), which is a measure of the total body load of a drug. The oral bioavailability can be compared by

$$\text{Bioavailability} = \frac{\text{AUC}_{\text{oral}}}{\text{AUC}_{\text{iv}}}$$

4.8.3 Hepatic Drug Clearance

The main means of removing a drug from the central compartment is by hepatic drug metabolism. The ability of the liver to eliminate a drug is related to the hepatic blood flow and the intrinsic clearance of the liver. When intrinsic clearance is much greater than hepatic blood flow, the liver metabolizes and extracts all the drug from the blood presented to it, and the higher the blood flow through the liver, the more drug will be extracted from it. On the other hand, if the intrinsic clearance is much less than blood flow, then the hepatic clearance is dependent on the rate of metabolism. These two extremes are called *flow-limited* and *metabolism-limited extraction*, respectively. Examples of the former are propranolol, and lignocaine, and of the latter antipyrine. The ability of the liver to clear a drug from the blood is dependent not only on the metabolic activity of the organ but also on factors that influence the hepatic blood flow, such as cardiac output and redistribution of blood during exercise.

4.8.4 Tissue Distribution Prediction Models for PBPK

PBPK modeling attempts to predict ADME parameters using mathematical modeling of *in vitro* and preclinical derived data. There are some main assumptions to generic PBPK models related to compound distribution. These include the following:

- Distribution is mainly a passive process with no significant active transport involvement.
- Distribution into tissues is rate limited primarily by site-specific blood flow.
- Each tissue is viewed as a well-stirred compartment.
- Permeability across the membrane does not hinder or limit the ability of compounds to distribute into tissues.

Several mathematical models to predict distribution of drugs into various organs and tissues have been proposed. Input data generally required for these models include both parameters related to the compound and to the system. Compound-related input parameters are $\log P$, pK_a , and blood plasma partitioning, while system-related parameters are the volume of lipids, phospholipids, and water in plasma and tissues, and the pH. The models aim to estimate the partition coefficients (K_p). Currently, it is common practice to use a number of the proposed models for predicting distribution parameters and compare them across known data sets to determine which model is most suitable. Five commonly used distribution models are described in Table 4.10. A major limitation with PBPK modeling predictions is lack of accounting for the presence of active uptake components, which can lead to a lack of correlation with *in vivo* data derived from preclinical species. Efforts to improve prediction models by incorporating transport parameters are on-going and are described in the literature [104,105].

4.9 CLINICAL IMPLICATIONS OF ALTERED DRUG DISPOSITION

Understanding the role of disposition in the pharmacokinetics of a drug is essential both for drug development and also for clinicians. The latter group must understand how the dosage of products is ascertained so that they can use the drug optimally in all groups of patients, appreciate that subgroups of patients may be at risk during therapy, and understand any limitations. This is particularly important for drugs with a low therapeutic index. An example of a group at risk is patients with deficient renal function. It is crucial to carefully monitor their response to drugs excreted predominantly by the kidney, for example, digoxin and aminoglycoside antibiotics, to avoid adverse effects.

4.9.1 Absorption

Absorption plays an important role in a clinical context and this can be illustrated, for example, in that the low oral bioavailability of many drugs limits their route of administration. For example, heparin is not absorbed from the GI track because of its size and charge, and it is therefore administered by injection, intravenously in emergency situations, and also routinely by patients at home subcutaneously [112]. On the other hand, treatment of *Clostridium difficile* infection resident in the gut by vancomycin has taken advantage of its poor GI absorption, which gives rise to high local concentrations in the colon [113].

4.9.2 Renal Elimination

Treatment of poisoning or drug overdose is often concentrated on minimizing absorption and also on increasing the elimination of the toxin. In many cases, the latter may

TABLE 4.10 Commonly Used Models for Predicting Distribution Parameters

Prediction Model (Reference)	Input Data	Output Data	Important Assumptions	Accurately Predicts	Mispredictions/ Additional Information
Poulin and Theil [106]	$\log P$, fup, pK_a (compound)	Partition coefficients Pt:p based on volumes of lipid, phospholipids water, and plasma proteins of each tissue	Lipid subcompartment mainly phospholipids, passive diffusion. Equation 4.1: homogeneous distribution; Equation 4.2: nonhomogeneous distribution	Acids, bases, and neutral compounds	Zwitterions and some acids and bases. Improvements to method have been published
Berezhkovskiy [107]	$\log P$, fup, pK_a	Same as Poulin model	Same as Poulin and Theil	Modified Poulin model	Additionally considers the exchange of drugs between compartments and peripheral drug elimination
Rodgers <i>et al.</i> [108]	$\log P$, fup, pK_a , BP	Same as Poulin model	Passive distribution and nonsaturating mechanisms. Electrostatic interactions between ionized compounds (bases) and anionic phospholipids (based on B:P). Interactions with intracellular neutral phospholipids and neutral lipids (based on olive oil–water partition). Consideration of interactions with intracellular neutral phospholipids and neutral lipids	Moderate to strong bases and improved prediction for zwitterions	Peripheral elimination, binding to tissue constituents other than phospholipids and when there is active transport

Willman <i>et al.</i> , PK-Sim [109]	$\log P$, f_{up} , pK_a , estimated RBC, membrane affinity	Same as Poulin model	Well-stirred system	Moderate to strong bases	<i>In silico</i> measured membrane affinity is used as a marker of lipophilicity
Schmitt [110]	$\log P$, f_{up} , pK_a , membrane affinity	Same as Poulin model but includes neutral lipids, neutral and acidic phospholipids, and proteins of each tissue	Lipid subcompartment consists of neutral lipids, neutral phospholipids, and acidic phospholipids	Class- independent model	Recommends use of membrane affinity to describe binding to phospholipids, if unknown can apply $\log P$ as an approximation. Accounts for electrostatic interactions between charged molecules at physiological pH with acidic phospholipids. Considers the difference in pH of tissues and plasma

be achieved by altering the pH of the urine. For example, acute aspirin or phenobarbitone poisoning is treated by alkalization of the urine. To achieve this, treatment with intravenous bicarbonate infusion is used and this may raise the urine pH between 7.5 and 8.1. As a result, the plasma half-life of aspirin has been shown to decrease from 19.4 h in control patients to 5.0 h in the treated group providing an effective means of removing the toxin [114]. Similarly, the renal clearance of phenobarbitone can be increased from 0.8 to 5.1 mL/h/kg in patients treated with sodium bicarbonate [115]. Although, theoretically, similar advantages may be gained from acidification of the urine for accelerating the clearance of basic drugs such as amphetamine or phencyclidine, there are significant risks associated with this procedure, such as acute renal failure and acid–base/electrolyte disturbances. Acidification of urine is therefore not recommended as a therapeutic method for treatment of overdose.

4.9.3 Transporter-Mediated Distribution

The distribution of many drugs is regulated by their uptake and efflux into body compartments and organs regulated by their affinity for various transporter systems as discussed in Section 4.5. Interference with transporter systems was used to clinical advantage during the World War II when penicillin was still in short supply. Doctors maximized its efficacy by coadministration of probenacid, which competitively inhibits its secretion from the renal tubules [116]. These transporters also of course transport endogenous ligands, for example, bilirubin, and indeed Campbell and coworkers [117] have suggested that the unconjugated hyperbilirubinemia induced during indinavir, rifamycin SV, and cyclosporine A therapy may be partly caused by competition and resultant inhibition of OATP1B1-mediated bilirubin uptake.

Coadministration of drugs is commonplace in pharmacy, and adverse drug–drug interactions can result in changes in both pharmacokinetics and pharmacodynamics. These interactions can occur during GI absorption, by interference with plasma protein binding, or with carrier-mediated transport (including hepatic or renal uptake and biliary or urinary excretion) or by metabolism. The latter mechanism is well established and has received a great deal of attention (reviewed by Campbell *et al.* [117] and discussed in detail elsewhere in this volume); however, the hepatic clearance of many poorly metabolized drugs has been found to be determined by hepatic uptake. Competition between different classes of drugs for the uptake transporter mechanisms is recognized as a mechanism responsible for several clinically significant drug–drug interactions. One of the classes of drugs involved in these interactions is the cholesterol lowering 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors, commonly referred to as the *statins*. The major target site of action for these drugs is the liver and they are taken up into hepatocytes by the organic anion transporter polypeptide OATP family, as mentioned previously in Section 4.5.1.2. Coadministration of various drugs has been reported to increase the plasma concentrations of statins [118] and this can occasionally lead to severe side effects such as myopathy and rhabdomyolysis [119,120]. Cyclosporin A interacts with the statins that are not appreciably metabolized in the liver, and the interaction with cerivastatin [121] and pitavastatin [122] has been demonstrated to occur because the cyclosporine A inhibits OATP1B1-mediated uptake. Hirano and coworkers [122] have predicted the degree of inhibition of OATP1B1 in humans *in vivo* by relating the blood unbound fraction of the inhibitor, the concentration of the inhibitor present at the inlet to the liver, and the *in vitro* K_i value for

inhibition of transport by OATP1B1 (measured in cultured HEK293 cells) for several compounds. As a result of their calculations, they have suggested that cyclosporine A, rifampicin, rifamycin SV, clarithromycin, and indinavar would interact with pitavastatin in a clinical situation to increase the plasma concentration, affect its cholesterol lowering activity, and more importantly cause side effects. Caution should also be advocated with inhibitors of OAT-mediated transport such as cephalosporins [122]. The occurrence of drug–drug interactions through competition and inhibition of transporter mechanisms has been extensively reviewed by Shitara *et al.* [123], and they constitute a major contribution to clinical adverse drug reactions, especially when the incidence of polypharmacy is considered.

4.10 SUMMARY

All the parameters affecting distribution, that is, physicochemical and physiological factors, and the action of metabolism and transporters, act together to determine the volume of distribution of drugs, and an understanding of these processes leads to better decision making about drug development and therapeutic use by pharmaceutical scientists and clinicians. To improve this decision-making process, the way forward should be to develop better models for future use concentrating on *in vitro* methods that allow accurate extrapolation to the *in vivo* patient situation. Strategies should be in place to encourage development in the areas of safety evaluation of candidate pharmaceuticals and minimize attrition in the drug discovery process.

5.1 SUMMARY

Of the 49 members of the ATP-binding cassette (ABC) family of proteins, the majority harness the energy of ATP hydrolysis to facilitate a unidirectional efflux of substrates from the cytoplasm and inner leaflet of the lipid bilayer to the extracellular space. Each of these proteins share highly conserved amino acid sequences that permit their classification into the ABC superfamily. These motifs lie within the nucleotide binding domains (NBDs) and include the Walker A, Walker B, and Signature C motifs. Importantly, their structures differ substantially in the substrate binding regions, ensuring the transport of a wide range of substrates. A large number of small-molecule therapeutics have been identified as substrates of at least one ABC transport pump. P-glycoprotein (P-gp), which is encoded by the *ABCB1* gene; multidrug-resistance-associated protein 1 (MRP1), which is encoded by the *ABCC1* gene; and breast cancer resistance protein, which is encoded by the *ABCG2* gene, in particular, are known to confer a multidrug resistance (MDR) phenotype. Therapeutics vulnerable to efflux

by this family of proteins include the anthracycline antibiotics and tyrosine kinase inhibitors used in the treatment of cancer, antivirals used to treat HIV, antihistamines used in the treatment of allergies, and immunosuppressants used to prevent graft rejection. Despite their well-established role in the onset of drug resistance, reversal of the MDR phenomenon by targeting the proteins through molecular mechanisms such as small interfering RNA (siRNA) or small-molecule inhibitors such as verapamil, or the more specific second- and third-generation inhibitors such as dexverapamil and tariquidar, respectively, have yielded limited results. To date, the ABC transporters are not targeted in adjuvant therapy and MDR continues to hamper many chemotherapy regimes. Further confounding the role of these proteins in drug response is genetic variation, particularly, single nucleotide polymorphisms (SNPs). This variation, which is often evident in populations of distinct evolutionary history, may manifest itself either through differences in drug efficacy between populations or through the onset of adverse effects. While the effect of such genetic variation is often subtle, loss-of-function mutations in the ABC genes are also common and may lead to severe diseases. Examples include cystic fibrosis (CF) and Tangier disease, which result from mutations in *ABCC7* and *ABCA1*, respectively. Each member of the ABC superfamily contributes to drug resistance and/or drug response in a unique manner that is dependent on the protein location, the specific drug, and the genetic history of the individual. Within this chapter, the role of the ABC transport proteins on drug efficacy and resistance is explored. Efforts to disrupt ABC-mediated drug resistance are discussed, and the influence of polymorphisms and mutations on protein function is also assessed.

5.2 INTRODUCTION TO THE ABC FAMILY OF TRANSPORT PROTEINS

5.2.1 Classification of the ABC Family

The ABC superfamily is the largest family of membrane-bound proteins in biology. To date, 49 members have been identified, and although some have functions other than substrate transport across lipid bilayers, each possess key sequence motifs and ATP-binding domain organization that permits their classification into one of seven subclasses, ABCA–ABCG [1,2]. While many of the genes that encode the ABC proteins are scattered throughout the genome, several reside in close proximity to each other, most often encoding members of the same subclass. Furthermore, while some of the ABC transport proteins are expressed ubiquitously throughout the body, others remain localized to specific tissue types where they transport physiological substrates that are required by that particular tissue or organ. A complete summary of ABC localization and function is presented in Table 5.1.

5.2.2 Protein Structure and Function

In eukaryotic cells, the majority of the ABC transport proteins are responsible for a unidirectional, active transfer of substrates across lipid bilayers, from the cytoplasm to the extracellular space. In some instances, where ABC proteins are localized to the lipid bilayer membranes of intracellular vesicles such as lysosomes or endosomes, substrates are trafficked from the cytoplasm into the vesicular compartments for further processing or efflux into the extracellular space [12,13]. Members of the ABCE and

TABLE 5.1 Location of Genes Encoding Members of the ABC Superfamily of Proteins, their Cellular/Tissue Localization and their Physiological Substrates

Gene Name	Gene Location	Cellular/Tissue Localization	Physiological Substrate/Function	References
ABCA1	9q31.1	Brain and liver	Lipids (HDL and cholesterol)	1–4
ABCA2	9p34	Brain, monocytes	Steroid derivatives, lipids	
ABCA3	16p13.3	Lung (alveolar type II cells)	Pulmonary surfactant	
ABCA4	1p22.1-p21	Retina	Retinylidene phospholipid complexes	
ABCA5	17q24	Intracellular localization; skeletal muscle, kidney, liver, placenta	Unknown; possibly lysosomal substrates	
ABCA6	17q24	Ubiquitous	Unknown; possibly macrophage lipids	1–3, 5, 6
ABCA7	19p13.3	Myelolymphatic tissues, keratinocytes	Phospholipids, including phosphatidylcholine	
ABCA8	17q24	Heart, skeletal muscle, liver	Unknown	
ABCA9	17q24	Ubiquitous	Unknown	
ABCA10	17q24	Ubiquitous, particularly in the intestinal tract	Unknown; possibly lipid transport	
ABCA12	2q34	Keratinocytes, stomach	Lipids	
ABCA13	7p11-q11	Trachea, testis, bone marrow	Unknown	
ABCB1	7q21	Intestine, liver, kidney, placenta, Blood brain barrier (BBB)	Multidrug resistance	
ABCB2	6p21	All cells	Peptide transport	
ABCB3	6p21	All cells	Peptide transport	
ABCB4	7q21.1	Liver	Unknown	1–3, 5
ABCB5	7p14	Ubiquitous	Unknown	
ABCB6	2q36	Mitochondria	Iron transport	
ABCB7	Xq12-q13	Mitochondria	Fe/S cluster transport	
ABCB8	7q36	Mitochondria	Unknown	
ABCB9	12q24	Heart, brain	Unknown	2, 7, 8
ABCB10	1q24	Mitochondria	Unknown	
ABCB11	2q24	Liver	Bile salts	
ABCC1	16p13.1	Ubiquitous	Organic anion efflux	1–3, 5

(continued overleaf)

TABLE 5.1 (Continued)

Gene Name	Gene Location	Cellular/Tissue Localization	Physiological Substrate/Function	References
ABCC2	10q24	Liver, kidney, intestine	Organic anion efflux	
ABCC3	17q21.3	Pancreas, kidney, intestine, liver, adrenal gland	Organic anion efflux	
ABCC4	13q32	Prostate, testis, ovary, intestine, pancreas, lung	Nucleoside transport	
ABCC5	3q27	Ubiquitous	Nucleoside transport	
ABCC6	16p13.1	Liver, kidney	Unknown	
ABCC7	7q31.2	Exocrine tissue	Chloride ion channel	
ABCC8	11p15.1	Pancreas	Sulfonylurea receptor	
ABCC9	12p12.1	Heart, muscle	Unknown	
ABCC10	6p21	Liver, heart, kidney	Unknown	
ABCC11	16q11-q12	Ubiquitous	Unknown	
ABCC12	16q11-q12	Ubiquitous	Unknown	
ABCD1	Xq28	Peroxisomes; ubiquitous	Acyl CoA, VLCFAs	9
ABCD2	12q11-q12	Peroxisomes; ubiquitous	VLCFA CoAs	
ABCD3	1p22-p21	Peroxisomes; ubiquitous	LCFA CoAs	
ABCD4	14q24.3	Peroxisomes	Unknown	
ABCE1	4q31	Ovary, testes, spleen	Oligoadenylate binding protein	2,10
ABCF1	6p21.33	Ubiquitous	Not Applicable (NA)	2
ABCF2	7q36	Ubiquitous	NA	
ABCF3	3q25	Ubiquitous	NA	
ABCG1	21q22.3	Adipocytes, macrophages	Cholesterol and Phospholipids	2,11
ABCG2	4q22	Placenta, intestine, breast, liver	Toxin efflux, drug resistance	
ABCG4	11q23	Adipocytes, macrophages	Cholesterol and phospholipids	
ABCG5	2p21	Liver hepatocytes, enterocytes in small intestine and colon	Lipophilic cholesterol	
ABCG8	2p21	Liver hepatocytes, enterocytes in small intestine and colon	Lipophilic cholesterol	

Abbreviations: VLCFA, very-long-chain fatty acid; LCFA, long-chain fatty acid.

Source: Adapted from Ref. 2.

ABCF subclasses do not function as membrane-bound transporters but are instead involved in ribosome biogenesis and translation initiation and elongation [10,14]. As these two subclasses do not influence the pharmacokinetics of drugs, they are not discussed further in this chapter.

Functional ABC transport proteins possess a minimum of two transmembrane domains (TMDs) with each TMD containing four to eight transmembrane (TM) helices. These not only permit a passageway for substrate transport but also form a cavity for drug binding known as the ligand binding domain (LBD) [3]. Attached to the TMDs are cytosolic NBDs that facilitate the binding and hydrolysis of ATP. By harnessing the energy of ATP hydrolysis, active transport of substrates across lipid bilayers, and often against chemical gradients, may occur [5]. Although the specific mechanism of substrate transport has not been completely defined, it is believed that a conformational change in the arrangement of the TMDs occurs following NBD dimerization. This subsequently alters substrate binding affinity and opens up the LBD to the extracellular space [15].

The NBDs, unlike the TMDs, are highly homologous across the ABC superfamily and feature a number of sequence motifs essential for protein function. The Walker A motif and the A-loop, which is a single tyrosine residue ~25 amino acids upstream of Walker A [16], have both been shown to be essential for ATP binding and hydrolysis [5,17,18], while other sequences including Walker B, the D-loop, H-loop, Q-loop, and the Signature C motif (LSGGQ), which is unique to the ABC transport proteins [19], are believed to bind diatomic metals such as Mg^{2+} and contribute to the binding and hydrolysis of ATP via their arrangement during NBD dimerization [16,20]. ATP initially binds to only a single NBD before dimerization of the two NBD occurs [21]. During dimerization, ATP is sandwiched between the two NBDs, in a binding cavity composed of the Signature C motif and D-loop from one NBD and the Walker A, Walker B, A-loop, H-loop, and Q-loop from the other NBD [22].

A number of ABC transport proteins are known as *half-transport proteins* and comprise only a single TMD and NBD each (Fig. 5.1) These include ABCB2, ABCB3, ABCB6, ABCB7, ABCB8, ABCB9, and ABCB10, as well as the four members of the ABCD subclass and the five members of the ABCG subclass [3]. In these cases, transport function is only acquired after dimerization between two or three half-transport protein members of the same subclass. In some instances, a homodimer may form, such as with ABCD1 [23] and BCRP (breast cancer resistance protein) [24]. In other cases, however, heterodimer complexes will be formed before integration into the lipid bilayers. This protein interaction was shown to exist between ABCG5 and ABCG8 [25], and it is well established that ABCB2 forms a functional heterodimer with ABCB3 [3].

With the exception of those in the ABCE and ABCF subclasses, the remaining ABC proteins are known as *full transporters*, each possessing at least two TMDs and two NBDs (Fig. 5.1). Each member of the ABCA subclass possesses this general structure as does the well-established ABC transporter P-gp, which was originally discovered in 1976 in MDR Chinese hamster ovary (CHO) cells [26]. The crystallization of mouse P-gp, which features 87% sequence homology to human P-gp, highlighted many of the structural features that give rise to protein function. These included substrate “entry portals” that are open to the inner leaflet of the lipid bilayer and ligand binding cavity of ~6000 Å³ that houses 73 residues capable of substrate binding [27]. A smaller group of “full transporters” are all classified into the ABCC subclass feature an additional N-terminal TMD and linker region (Fig. 5.1). These include ABCC1, ABCC2, ABCC3,

Figure 5.1 Schematic diagram showing the topology of the three major ABC transport proteins. (a) ABCG2 (BCRP) is a half transporter, comprising only a single transmembrane domain made up of six transmembrane helices and a single cytoplasmic nucleotide binding domain. (b) ABCB1 (P-glycoprotein) is a full transporter with two transmembrane domains and two nucleotide binding domains. (c) ABCC1 (MRP1) is also a full transporter but with an additional transmembrane domain (TM0) comprising five transmembrane helices. Each of these proteins contains glycosylation sites that are indicated by “*.” *Source:* Adapted from Ref. 5. (See color insert.)

ABCC6, ABCC8, ABCC9, and ABCC10. MRP1 is one of the most well-established ABC transport proteins possessing this structural property. Sharing less than 20% amino acid identity with P-gp [28], MRP1 features not only an additional TMD, which comprises five TM segments [29], but also a 13-residue amino acid sequence deletion between the Walker A and Walker B sequence motifs in the NBD1 [28]. The importance of this deletion was made evident when it was shown that insertion of the 13 residues from P-gp renders MRP1 inactive [30]. Although the additional cytoplasmic linker region (L_0) was shown to be vital for substrate transport, loss of TMD₀ does not greatly affect substrate transport [31]. Two other “full transporters” possessing an additional TMD are the sulfonyleurea receptors ABCC8 and ABCC9. These proteins function only in complex with their K^+ channel counterparts despite possessing three TMDs. Each protein remains in the cytoplasm until being activated by ATP/ADP, at which point hetero-octameric complexes are formed with the potassium channels Kir6.1 and Kir6.2,

respectively. It is in this position that ABCC8 and ABCC9 regulate the permeability of these potassium channels [32].

5.3 TRANSPORT OF SMALL MOLECULES BY ABC PROTEINS

5.3.1 Specificity of Substrate Binding

Most pharmacological substrates are transported by more than one ABC protein. As highlighted in Table 5.2, many anticancer drugs are vulnerable to efflux via four well-researched ABC drug transporters; P-gp, MRP1, MRP2, and BCRP. For example, the well-established topoisomerase poisons, etoposide and teniposide, are substrates of these three ABC drug transporters, while the taxanes, paclitaxel and docetaxel, are not known to be substrates of either MRP1 or BCRP, yet are transported by P-gp [5].

Generally, P-gp will transport neutral or positively charged hydrophobic molecules, whereas MRP1 is predominately an anionic transporter [51]. Binding and efflux of substrates is, however, selective, and the structural properties of substrates, in combination with the arrangement of amino acids within the LBDs, will determine this specificity. Great efforts have been made, with varying degrees of success, to establish the basis for selectivity in drug binding, particularly with respect to P-gp. Through analytical comparison of 100 known P-gp substrate structures, Seelig and colleagues attempted to determine the structural properties of P-gp substrates. A theoretical model was presented that was based on the spatial separation of essential electron-donor groups, and in this model, it was postulated that each hydrophobic substrate must feature two electron-donor groups $2.5 + 0.3$ Å apart, two electron-donor groups $4.6 + 0.6$ Å apart, or three electron-donor groups with the outer two groups separated by $4.6 + 0.6$ Å [52,53].

Alternative methods focused on mapping the drug substrate binding regions of P-gp, using photoaffinity analogs of established P-gp substrates. Such methods revealed several specific binding sites within the LBD. For example, [125 I]iodomycin, a derivative of daunorubicin, was found to be bound to amino acids 230–312 (located in TM helices 4 and 5 and the cytoplasmic loop joining them) in isolated hamster P-gp [54]. The prazosin analog [125 I]iodoarylazidoprazosin was found to bind to three sites (amino acids 248–312 in TM helices 4–5, 758–800 beyond TMD8, and 1160–1218 in the second NBD) following tricine/PAGE and HPLC separation of 125 I-labeled fragments and subsequent Edman sequencing [55]. Similarly, benzophenone analogs of paclitaxel were used to identify two binding sites at amino acids 683–760, which lie in TM helices 7–8, and 985–1088, which begin in TM helix 12 and end after the Walker A motif in the second NBD [56]. Similar studies have identified the binding sites of analogs of azidopine [57], dextriguldipine [58], cyclosporin A [59], and others [60].

Further evidence to indicate that multiple drug binding sites exist within a single LBD was reported following the crystallization of stereoisomeric QZ-59 compounds with mammalian P-gp. A range of distinct residues promoted drug binding, and although it was shown that the same residue may interact with molecules bound at different sites, the specific role of these residues in each interaction differs [27]. Two residues previously identified as being protected by MTS-verapamil labeling and therefore located in verapamil binding sites [61,62] were found also to interact with the QZ-59 compounds. A further 16 residues identified as interacting with the QZ-59

TABLE 5.2 Summary of Pharmacological Substrates of the Three Primary ABC Drug Transporters

Drug	Drug Class/Type	Indication	P-gp	MRP1	MRP2	BCRP
Vincristine	Vinca alkyloid	Cancer	+	+	+33	
Vinblastine			+	+	+ 34	
Doxorubicin	Anthracycline antibiotic		+	+	+ 35	+
Daunorubicin			+	+		+ ^a
Paclitaxel	Taxane		+			
Docetaxel			+		+ 36	
Etoposide	Epipodophyllotoxin		+	+	+ 35	+
Teniposide			+	+	+ 37	+
Topotecan	Camptothecin		+	+	+38	+
Irinotecan				+		+
Bisantrene	Anthracene		+			+ ^a
Mitoxantrone			+			+
Methotrexate	Folic acid analog			+	+ 39	+
Melphalan	Alkylating agent			+ ^b		
Cyclophosphamide				+ ^b	+ 40	
Imatinib mesylate	Tyrosine kinase inhibitor		+	+		+
Gefitinib			+	+		+
Flavopiridol	Cyclin-dependant kinase inhibitor					+
Ritonavir	Antiviral	HIV	+	+	+ 41	
Saquinavir			+	+	+ 41	
Nelfinavir			+			
Morphine	Opioid analgesic	Severe pain	+		+ 42	
Fexofenadine	Antihistamine	Seasonal allergic rhinitis. Urticaria	+		+ ^c 43	
Cimetidine	H ₂ -receptor antagonists	Duodenal and Gastric Ulcers	+			
Cyclosporin A	Immunosuppressant	Graft rejection	+		+ 44	

Tacrolimus		Adjunct to liver, kidney, lung, and heart allograft transplantation	+		
Amiodarone	Antiarrhythmics	Severe tachyarrhythmias	+	+ ^d 45	
Propafenone			+		
Felbamate	Anticonvulsant	Epilepsy	+		
Topiramate			+	– 46	
Lovastatin	Statin	Hypercholesterolemia	+ ^e	– 47	
Simvastatin			+ ^e	– 47	
Rosuvastatin				+ 47	+
Pravastatin				+ 48	+
Ondansetron	Antiemetics	Nausea	+		
Digoxin	Cardiac glycoside	Chronic heart failure and atrial fibrillation	+		
Ivermectin	Antinematodal	Onchocerciasis, intestinal strongyloidiasis	+		
Verapamil	Ca ²⁺ channel blocker	Hypertension, tachyarrhythmia, angina	+		
Nifedipine			+		
Diltiazem			+		
Trifluoperazine	Phenothiazine antipsychotic	Chronic psychotic disorders, anxiety, and alcoholism	+		
Chlorpromazine		Acute functional psychoses	+		
<i>Trans</i> -flupentixol	Thioxanthene neuroleptic	Chronic schizophrenia	+		
Propranolol	β-Adrenergic blocker	Hypertension, angina	+		

(continued overleaf)

TABLE 5.2 (Continued)

Drug	Drug Class/Type	Indication	P-gp	MRP1	MRP2	BCRP
Difloxacin	Quinalone antibiotic	Susceptible infections		+		
Erythromycin	Macrolide antibiotic		+		+ 49	
Gramicidin A	Antibiotic		+			
Ciprofloxacin	Fluoroquinolone antibiotic					+
Norfloxacin						+
Dexamethasone	Glucocorticoid	Corticosteroid responsive conditions	+		+ ^d 50	
Disulfiram	Alcohol deterrent	Chronic alcoholism	+			

Where information is not from Ref. 5, reference is included in the table. Blank cells indicate no information was obtained. “-” indicates MRP2 was confirmed as having no influence on the drug pharmacokinetics.

^aTransported by ABCG2R482T mutant only.

^bTransported as glutathione conjugates.

^cIn mice may be species specific.

^dStudy found ABCC2 transcription and expression increased as a result of drug exposure. Impact on transport is unclear.

^eLater studies suggest neither drugs are transported by MRP2 47. “+” indicates the drug is transported by the ABC protein.

Source: Adapted from Ref. 5.

compounds were also highlighted for their role in drug binding by an independent study that utilized arginine-scanning mutagenesis to determine residues important in drug translocation. By introducing arginine residues at each position in TM helices 2–12 of a P-gp processing mutant (G251V) and assessing their effect on protein maturation, the location of each residue in relation to possible drug binding sites was established. Several arginine substitutions located on the internal surface of the LBD were shown to reduce verapamil binding affinity 10-fold, while others promoted a 10-fold increase in binding affinity of rhodamine B, again highlighting that multiple binding sites exist within the LBD, promoting the selectivity of P-gp substrates [63].

Some examples of pharmacological agents that are transported by P-gp, MRP1, and BCRP are presented in Table 5.2.

5.3.2 Role of Glutathione in ABCC Subfamily Activity

Despite primarily transporting organic and anionic molecules, MRP1 transports a greater number of substrates than P-gp [64]. This phenomenon has been attributed to the essential role of glutathione (GSH) in drug transport mediated by members of the ABCC subfamily, particularly, MRP1 and MRP2. Although the exact mechanisms by which GSH aids in drug transport remains unclear, evidence suggests that the reducing tripeptide either binds to MRP1 and induces a conformational change to subsequently enhance the transport of hydrophobic compounds or is cotransported with the drugs [31]. Importantly, GSH is required not only for the MRP1-mediated efflux of therapeutics but also for the transport of several physiological substrates, including the well-established substrate of MRP1, leukotriene C₄ (LTC₄) [65]. Other endogenous molecules such as prostaglandin (PG) A₂, 4-hydroxynonenal, and the PGD₂ derivative 15-deoxy- $\Delta^{12,14}$ -PGJ₂ are also cotransported with GSH, in each case as GSH-conjugates [65].

GSH itself is a poor substrate of MRP1 and can only be transported in the presence of hydrophobic compounds. For example, vincristine, a vinca alkaloid used in the treatment of various cancers, cannot be transported by MRP1 alone. In the presence of GSH, however, both vincristine and GSH accumulate in vesicles expressing the transporter, indicating that GSH is cotransported with the drug [66] in a mechanism where both substrates rely on each other for transport. Studies using inside-out membrane vesicles isolated from MRP1-overexpressing cells indicate that without physiological concentrations of GSH present, MRP1 lacks the ability to transport many unmodified anticancer drugs [67,68]. Unlike the endogenous substrates of MRP1, however, there is no evidence to indicate that conjugates form between GSH and xenobiotic substrates. Instead it is believed that these agents are effluxed together with GSH in a simple cotransport mechanism or following conformational changes to MRP1, they are induced when GSH and the drug bind to the protein. Currently, little is known about the mechanism by which GSH and substrates induce conformational changes to MRP1. However, several studies have been carried out to determine possible substrate–GSH binding sites. Photoaffinity labeling techniques using derivatives of MRP1 substrates such as [H₃]LTC₄, iodoaryl-azido GSH (IAAGSH), and azidophenacyl GSH (APAGSH) have predicted the location of various substrate binding sites within the protein [69]. In the case of [H₃]LTC₄, it was suggested that substrate binding sites may exist within the lipid bilayer, possibly in the final two TM segments of TMD1 and TMD2 [69]. Site-directed mutagenesis studies have also revealed several sites in the TMDs of MRP1 that

may be important in the binding of GSH, such as Lys332 and His335 in α -helix 6 of TMD2 [70,71]. Using homology models to explore the influence of a range of proline substitutions in various TM α -helices of MRP1, it has also been shown that mutating Pro478 of TM9 to an alanine residue selectively reduces LTC₄ transport [72]. Similar studies aimed at determining substrate binding sites of MRP1 inhibitors showed preferential cross-linking of the radiolabeled photoactive compounds to segments within the third (COOH-proximal) TMD [73,74], suggesting that MRP1 has more than one drug binding site. It is also possible that MRP1 substrates such as GSH form individual, yet not necessarily unique, binding sites within a common binding pocket in the transporter [65].

Like MRP1, the mechanisms by which GSH facilitates MRP2-mediated drug transport is unclear. Early studies revealed GSH-stimulated vinblastine transport by rabbit MRP2 expressed in the insect cell line Sf9 [75]. Similarly a 10-fold increase in GSH was observed in the canine cell line MDCKII transfected with MRP2 versus wild-type cells, leading to the conclusion that MRP2 facilitates a low affinity transport of GSH [76]. Subsequent studies using MDCKII reported similar findings in the transport of vinblastine [34]. This study also found GSH to be cotransported with low concentrations of sulfinpyrazone; however, at high concentrations of the drug, transport of GSH was not observed, while transport of sulfinpyrazone continued [34]. It was hypothesized that two binding sites exist in MRP2, and at high concentrations, sulfinpyrazone will occupy both sites, preventing the cotransport of GSH, yet allowing sulfinpyrazone to be transported alone [34].

5.3.3 Influence of ABC Transporters on Drug Accumulation in Vesicles

Several ABC drug transporters localize to the lipid bilayer membranes of intracellular vesicles such as lysosomes and endosomes. From these locations, the drug transporters facilitate the active sequestration of various agents into the acidic compartments for drug efflux or redistribution away from the target. It was demonstrated that the ABC transport pump, ABCA3, localized to the lipid bilayers of lysosomes and multivesicular bodies where it conferred resistance to a range of cytotoxic agents including daunorubicin, mitoxantrone, etoposide, and vincristine. This drug resistance resulted from an ABCA3-mediated drug uptake into vesicles of low pH [12]. Earlier studies had also implicated the ABC transport proteins in the uptake of anticancer drugs into acidic vesicles of the membrane trafficking system. In 2003, Rajagopal and Simon provided evidence that in HeLa cells, MRP1, P-gp, and BCRP were not only localized to membranes of intracellular vesicles but their roles at these sites contributed to drug resistance phenotypes. Using a cell impermeable MRP1 inhibitor, it was highlighted that two separate pools of MRP1 were active within the cell and active sequestration of the drug by vesicular MRP1 alone was sufficient to confer drug resistance. In this study, doxorubicin was shown to colocalize in lysosomes with MRP1 and accumulation of the drug was prevented following pretreatment with verapamil, an ABC transport pump inhibitor [13,77]. In a separate study using HL-60 cells, it was reported that while the anthracycline antibiotic, doxorubicin, accumulated in acidic vesicles following passive diffusion of the lipid bilayer, and subsequent protonation of the compound, the zwitterionic compound, sulforhodamine 101, accumulated in the Golgi body following an MRP1-mediated uptake into the organelle [77].

5.4 INFLUENCE OF ABC ACTIVITY IN DRUG RESISTANCE

Although the ABC proteins have been shown to transport many therapeutic agents, with the cause of MDR being multifactorial, their influence on this phenomenon, especially *in vivo*, remains debatable. In a review of P-gp function in cancer, Ambudkar and colleagues suggested five points that should be met in order to declare an ABC transport protein responsible for drug resistance in a clinical setting. First, the protein should be expressed at a level comparable to that which is known, *in vitro*, to confer resistance. Second, this level should predict the degree of resistance, while in the third point, it was suggested that any increase in drug resistance during treatment should occur together with an increase in protein expression. The fourth point suggested that if the ABC protein is the sole contributor to resistance, then this resistance should be reversed with protein inhibition. Finally, it was suggested that any inhibitor would be advantageous as an adjuvant therapy [60].

To date, a total of 18 ABC transport proteins have been implicated in drug resistance [78]. Of these 18 proteins, only P-gp, MRP1, and BCRP have been identified on several occasions to contribute to the development of the MDR phenotype *in vivo*, and hence, greater attention will be paid to the role of these proteins in drug resistance. Although these proteins may confer resistance to drugs used in the treatment of many diseases, their influence on the efficacy of cancer therapy dominates the literature. As such, this chapter focuses on the role of the ABC proteins in cancer drug resistance.

5.4.1 ABCB1 (P-gp) and Cancer Drug Resistance

A large amount of clinical data correlates expression and function of P-gp with response to therapy in cancer patients. Two independent studies have drawn correlations between expression level of the protein and response to therapy in the treatment of breast cancer. One of these studies indicated that the presence of P-gp, which was increased 1.8-fold by prior exposure to chemotherapy, translated to a three- to fourfold greater chance of treatment failure [79], while the other reported a strong correlation between the extent of taxol and doxorubicin resistance in 359 resected breast cancer samples and the expression levels of P-gp [80]. Similar results were observed in nonsmall-cell lung carcinoma (NSCLC) where 68% of tumors that expressed P-gp were resistant to the drug paclitaxel, while those lacking the protein responded well to therapy [81]. In contrast, P-gp was overexpressed in only 2% of 67 metastatic glioma patients despite a high level of drug resistance observed in all patients. In this case, it was suggested that P-gp activity is just one mechanism contributing to the MDR phenotype [82]. Abe and colleagues supported these findings in 1998 reporting that only 4–23% of gliomas were P-gp positive. This study also highlighted that P-gp expression was higher in patients who had previously been exposed to chemotherapy, suggesting the protein played a role in acquired drug resistance [83]. P-gp has also been identified as a cause of drug resistance in leukemias and lymphomas, where expression of the protein is upregulated after exposure to chemotherapy. It is expressed in ~30% of all acute lymphoblastic leukemia (ALL) patients at diagnosis, and although studies have reported an association between its expression and patient response to therapy [84,85], these findings were contradicted by other studies [86–88].

5.4.2 ABCC1 (MRP1) and Cancer Drug Resistance

MRP1 is ubiquitously expressed throughout the body and as a result high levels of the protein have been identified in most cancer types. Unlike P-gp, MRP1 does not appear to contribute to MDR to any significant degree in metastatic breast cancer nor ALL. Despite this, MRP1 is associated with the development of MDR in a large number of tumor types including lung carcinomas and gliomas. The protein is regularly expressed in NSCLC where it correlates highly with a poor patient response to chemotherapy and overall survival [64,89]. These findings were described in a study that assessed MRP1 levels in 126 samples via immunohistochemistry. In this study, MRP1 levels were more highly expressed in stage 1 tumors versus late-stage tumors and were particularly high in patients who had not yet received chemotherapy, suggesting that the overexpression is inherent in NSCLC and not induced by chemotherapy exposure. It was also highlighted in the same study that although MRP1-positive tumors appear less aggressive, they are particularly resistant to chemotherapy [89]. Similar results have been reported in small-cell lung carcinoma (SCLC) where MRP1 expression is also elevated in patients who had a relapse [90]. Benyahia *et al.* reported that MRP1 was highly expressed in the vascular endothelial cells in 93% (14/15) of the glioma tumor samples examined. From this localization, it was proposed that MRP1 limits the uptake of drug into the brain tumor cells [91]. The protein was also found to be expressed along with MRP4 and MRP5 to the luminal side of brain capillary endothelial cells where again, it was proposed to influence drug penetration of the blood brain barrier [92]. The effect of MRP1 expression in human gliomas was also discussed in 2005 when a high level of expression was shown in 51% of the human glioma specimens and primary cell cultures examined. No difference between primary and recurrent glioma was observed, and it was subsequently concluded that MRP1-mediated drug resistance is intrinsic to glioma tumors [93].

5.4.3 ABCC2 (MRP2) and Cancer Drug Resistance

The effect of MRP2 on *in vivo* cancer drug resistance remains to be defined. However, it is clear that many agents used in the treatment of cancers are transported by the pump in *in vitro* studies. MRP2 was found to confer resistance to a large range of compounds including cisplatin and methotrexate. This resistance was highlighted after cisplatin resistance was successfully reversed using anti-MRP2 hammerhead ribozymes in the ovarian carcinoma cell line A2780RCIS [39]. MRP2-facilitated methotrexate resistance was also highlighted in an ovarian carcinoma cell line, with resistance observed following short-term exposure (1–4 h) of the drug [94]. Although overexpression of MRP2 has been shown to confer resistance to the tyrosine kinase inhibitor sorafenib in LLC-PK1 cells [95], earlier studies suggest that this is not common to all drugs of this class, with no active transport of erlotinib observed in MDCKII cells stably expressing MRP2 [96]. Other studies, using cell lines stably transfected with human MRP2, reveal that this protein confers resistance to etoposide, cisplatin, doxorubicin, and epirubicin. This resistance was up to 10-fold in the case of cisplatin and fourfold in the case of etoposide [35]. These results were supported in a study of drug resistance in esophageal squamous cell carcinoma (ESCC) treatment, which found that inhibition of MRP2 expression by siRNA reduced resistance to the 5-fluorouracil, doxorubicin, and cisplatin treatment regime [97]. Although *in vitro* studies had shown MRP2 to transport docetaxel, *in vivo* studies using MRP2 knockout mice revealed no difference in

drug pharmacokinetics compared to wild-type mice. When CYP3A and P-gp were also knocked out, however, (Cyp3a/Mdr1a/b/Mrp2^{-/-}) changes in the drug's pharmacokinetics were observed. These changes were evident when compared to both wild-type mice and Cyp3a/Mdr1a/b knockout mice proficient in MRP2, indicating MRP2 will reduce docetaxel exposure in the absence of both CYP3A and Mdr11/b [36].

5.4.4 ABCG2 (BCRP) and Cancer Drug Resistance

BCRP was originally identified by Doyle and colleagues [98] in 1998 in the MC7-AdrVp breast cancer cell line. Examination of BCRP and its role in drug resistance in leukemia patients has yielded a variety of results. In a study of 46 mixed lineage ALL samples, it was determined that BCRP was not only more highly expressed in the B-cell lineage compared to the T-cell lineage but also had a greater influence on MDR in these cells [99]. BCRP was also implicated in mitoxantrone efflux in 70% (21/30) of untreated ALL patients despite low mRNA levels being detected [100]. Furthermore, BCRP levels were found to be 10-fold higher in acute myeloid leukemia (AML) patients who did not achieve remission compared to those patients who responded well to therapy [101]. However, contradictory to these findings were reports that BCRP does not correlate to drug resistance in leukemia patients. One such report examining Ara-C resistance in 13 infants and 13 noninfants found that despite *ABCG2* mRNA expression being positively correlated to Ara-C resistance, the drug was not a substrate of the transporter and hence other mechanisms were responsible for this resistance [102]. Sauerbrey and colleagues also reported that although BCRP expression was lower in the T-cell lineage, there was no significant correlation between protein expression levels and response to therapy [103]. Similarly there are mixed reports on the influence of BCRP in drug resistance in solid tumors. In a recent study it was found that although there was no significant association between P-gp and MRP1 expression in SCLC patients' response to therapy and survival, there was a significant association between BCRP expression and tumor response to chemotherapy and progression-free survival [104].

5.4.5 Impact of Other ABC Transporters on MDR

Although there are few reports of the remaining ABC proteins influencing MDR *in vivo*, a substantial number of *in vitro* studies have provided evidence that implicates various ABC transport proteins in the onset of MDR. It was found that ABCA2 confers resistance to mitoxantrone in the BCRP1-negative GLC4-MITO cell line when compared to the GLC4 cell line [105], and it has also been established that the same protein confers resistance to the estrogen derivative, estramustine [106]. As previously mentioned, ABCA3 reportedly conferred resistance in leukemia cells to the anthracycline antibiotics, etoposide and vincristine, when localized to the lipid bilayer membranes of acidic vesicles [12]. This finding supported an earlier report that identified ABCA3 overexpression in pediatric AML using microarray technology. With a median expression level of threefold higher in patients who had failed to achieve remission following the first round of chemotherapy, it was suggested that ABCA3 conferred resistance to the anthracycline antibiotics in AML patients [107].

A greater number of ABCB members have been implicated in cancer drug resistance. Along with P-gp, both ABCB2 and ABCB3 have been shown to contribute

to mitoxantrone and etoposide/teniposide resistance [7,78], while both ABCB4 and ABCB11 have been implicated in resistance to paclitaxel [8]. ABCB5 has been shown to confer resistance to doxorubicin, camptothecin, and 5-fluorouracil [108]. One study that flagged ABCB5 as a contributor to doxorubicin resistance in malignant melanoma highlighted exclusive expression in a subpopulation of tumor stem cells. Blockade of the ABCB5 transporter using a specific inhibitory monoclonal antibody reversed doxorubicin resistance in G3361 melanoma cells, and the hypothesis was raised that targeting this transporter in an adjuvant therapy may enhance the efficacy of those agents used in the treatment of malignant melanoma [109]. The final member from the ABCB subfamily to be implicated in drug resistance is ABCB6 that has been shown *in vitro* to confer resistance to both cisplatin and camptothecin [78,110].

Like the ABCB subclass, a large number of ABCC subclass members have been shown to confer resistance to various anticancer agents. While MRP1 and MRP2 remain the most actively researched members of this subclass, ABCC3, ABCC4, ABCC5, ABCC6, ABCC10, and ABCC11 have all been shown to influence drug resistance phenotypes [78]. ABCC3 confers only a mild resistance to the vinca alkaloids, epipodophyllotoxins, methotrexate, and cisplatin [37]. Although the protein is able to transport organic compounds conjugated to GSH, experiments assessing GSH efflux suggested that ABCC3 cannot transport the tripeptide alone and does not require it for drug transport [37]. Evidence implicating ABCC4 in MDR phenotypes remains limited, although it has been suggested to be a possible target for cancer therapy. This is due to its role in the regulation of the intracellular concentrations of cAMP and the subsequent maturation of leukemic cells [111]. A report in 2005 concluded the transporter contributes to neuroblastoma prognosis through its activity in effluxing irinotecan and its active metabolite SN38 [112]. However, a later study assessing the systemic clearance of these agents in mice determined that ABCC4 did not influence their elimination, while P-gp did [113]. *In vitro* studies implicated ABCC4 in the resistance of cyclophosphamide and ifosfamide [114], topotecan and methotrexate [115], as well as camptothecin, SN-38, and other camptothecin derivatives [116] in HepG2 and HEK293. A larger number of substrates have been reported to be transported by ABCC5, yet it has also been highlighted that this transport is unlikely to contribute significantly to clinical MDR [117]. Various studies, each utilizing cells transfected with MRP5, have suggested a role for the protein in the transport of cisplatin, Oxaliplatin doxorubicin [118], etoposide, and teniposide [119]. Like many of the other members of the ABCC subclass, ABCC6, otherwise known as *MRP6*, has been shown to confer a low level of resistance to the anthracyclines, epipodophyllotoxins, and cisplatin [120]. Evidence to indicate this is, however, limited, and the suggestion has been made that like MRP5, MRP6 makes little contribution to clinical MDR [78]. After ruling out the influence of P-gp, BCRP, and various members of the ABCC family of drug transporters, it was recently shown that expression of ABCC10 (MRP7) confers resistance to vinorelbine in NSCLC cell lines [121]. This protein was also implicated in taxane resistance in transfected HEK293 cells where cellular accumulation of radiolabeled paclitaxel was reduced compared to cells transfected with a control plasmid [122]. The final member of the ABCC subclass that has been implicated in drug resistance is ABCC11. This protein was shown to confer resistance to 5-fluorouracil in a resistant subline of the PC-6 human SCLC cell line. In this case, resistance facilitated by MRP8 was reported at up to 25-fold [123].

5.5 INFLUENCE ON ADVERSE REACTIONS AND DRUG-DRUG INTERACTIONS

Drug-drug interactions (DDIs) manifest themselves clinically through altered pharmacokinetics, where one drug influences the absorption or disposition of another, and through altered pharmacodynamics, where drugs used in combination may produce additive, synergistic, or antagonistic effects [124]. Direct clinical evidence of P-gp inducing DDI is limited due to cross-specificity of P-gp substrates with the drug-metabolizing enzyme CYP3A4. While much of the current evidence indicates that CYP3A4 is a greater contributor to DDIs [124,125], it has been proposed that the ABC proteins contribute to DDI, and subsequent adverse side effects, following coadministration of antiretroviral agents used in the treatment of HIV with antifungals, antibiotics, cardiovascular agents, and recreational/illicit agents such as cocaine, lysergic acid diethylamide (LSD), marijuana, and 3,4-methylenedioxymethamphetamine (MDMA) [124].

While P-gp may not define drug disposition *in vivo* alone, its contribution to peak plasma concentrations and elimination rates of substrates with narrow therapeutic windows may be great enough to produce severe adverse reactions. This is the case with the cardiovascular drug digoxin, which is not metabolized by the cytochrome P450 family of enzymes but is a substrate of P-gp. Itraconazole, an antifungal agent that is known to modulate the function of P-gp, increases the plasma concentrations of digoxin while decreasing its renal clearance [126]. Similarly, the calcium channel blocker mibefradil was removed from the market as it increased the $C_{\max}$ and AUC of digoxin to levels that induced severe adverse reactions. [127]. P-gp was also implicated in DDIs between digoxin and rifampicin, an antibiotic used in the treatment of tuberculosis. In this case, the AUC of digoxin administered orally was significantly reduced when coadministered with rifampicin. This was attributed to a rifampicin-induced increase in the intestinal expression of P-gp, preventing the absorption of digoxin in the gut [128]. It should be noted, however, that although many studies have implicated digoxin in P-gp-mediated DDIs, a recent retrospective analysis of 123 such studies concluded that the majority of reported DDIs involving digoxin were not clinically significant [125].

The influence of P-gp on interactions between dopaminergic agonists used in the treatment of Parkinson's disease has also been assessed. While each of the agents examined were P-gp substrates, only bromocriptine inhibited substrate transport. The subsequent effect of this inhibition was evident on the intracellular transport of levodopa (L-dopa), which increased over twofold. With L-dopa, bromocriptine, and other dopaminergic agonists administered simultaneously in the treatment of Parkinson's disease, it was proposed that through its effect on P-gp function, bromocriptine could alter the disposition of L-dopa and subsequently induce an adverse effect as neurotoxicity [129].

5.6 MODULATION OF ABC PROTEIN FUNCTION

5.6.1 Molecular Mechanisms to Modulate ABC Function

Several molecular techniques have been adopted in an attempt to inhibit the function of the ABC drug transporters. P-gp targeting hammerhead ribozymes delivered via liposomes were utilized to achieve P-gp inhibition and reversal of vincristine resistance

in the breast cancer cell line MCF-7/R. This study, however, failed to achieve similar results in the MOLT-3/TMQ₈₀₀ cell line [130]. Successful inhibition of P-gp function in MOLT-3/TMQ₈₀₀ cell line was achieved, however, following transduction of MDR-1 hammerhead ribozymes into the cells. A retroviral vector containing Pol III was utilized to improve ribozyme activity and resulted in decreased levels of P-gp, along with an increase in vincristine sensitivity. On the basis of these results, it was suggested that the ribozyme targeting the translation initiation site was the most efficacious in reversing drug resistance [131].

Currently, gene silencing via the use of short siRNAs targeted toward the ABC transport proteins is proving successful in the reversal of drug resistance in *in vitro* studies. The efficacy of siRNAs targeted toward the *ABCB1* gene was revealed using the multidrug-resistant human pancreatic carcinoma and gastric carcinoma cell lines EPP85-181RDB and EPG85-257RDB. Expression of P-gp was reduced 91% at the mRNA and protein levels and this was correlated to significant improvements in the efficacy of daunorubicin. This reduction in drug resistance was reportedly at a level of 89% in EPP85-181RDB cells and 58% in EPG85-257RDB cells [132]. Successful inhibition of P-gp translation was also reported by Stege and colleagues in 2004. A complete reversal of resistance was achieved in the EPG85-257RDB cell line following exposure to an anti-P-gp short-hairpin RNA expression vector. This stable reversal of resistance was reportedly associated with a significant increase in intracellular accumulation of the anthracycline antibiotic daunorubicin [133].

5.6.2 ABC Modulators as Adjuvant Therapies

A large number of small molecules have been developed over the years, which modulate or inhibit the activity of the ABC transport proteins. Many of these molecules have entered clinical trials as adjuvant therapies, particularly in the treatment of cancer; however, the majority were not found to be clinically relevant, most often due to excessive adverse effects and toxicities at doses well below those required to inhibit the ABC proteins. These small molecules modulate the function of the ABC transport proteins through a number of mechanisms including competition at the drug substrate binding pocket, binding to high affinity sites in the NBD or through unique mechanisms.

Verapamil, cyclosporin A, and the phenothiazines, which act as competitors at the substrate binding site, are first-generation ABC inhibitors that were considered as adjuvant therapies for cancer treatment and they subsequently entered clinical trial. These compounds are associated with severe dose-limiting side effects that include cardiomyopathy, hypotension, and increased toxicity of the cytotoxic compounds. In the case of calcium channel blockers such as verapamil, adverse cardiovascular effects occur at dose concentrations lower than that required to inhibit the ABC transporters [134–136]. Clinical trials involving these first-generation inhibitors of ABC transporters indicated that although they may improve the efficacy of treatment in leukemia patients [137,138], the benefit in the treatment of solid tumors remains debatable. Early studies indicated that no advantage was gained in solid tumors, predominately due to the onset of cardiotoxicity at doses required to inhibit P-gp [139,140]. More recent studies, however, have reported that inclusion of verapamil in the treatment of doxorubicin-resistant metastatic breast cancer improved patient response without the onset of dose-limiting side effects [141].

The second-generation compounds dexverapamil and PSC833, which are analogs of verapamil and cyclosporin A, respectively, are associated with fewer and less intense

adverse effects. Their success in clinical trial, however, remains limited. Dexverapamil was assessed in combination with doxorubicin and epirubicin in patients with metastatic breast cancer, and although it was reported that inclusion of dexverapamil did not intensify anthracycline-associated cardiotoxicity, the number of patients achieving a complete response to therapy were limited [142,143]. Although the results obtained in these studies were considered promising, it could not be confirmed that this was a consequence of ABC transport inhibition. These conclusions were again reflected in another phase II trial in patients with advanced pancreatic cancer. The *in vivo* efficacy of PSC833 was assessed in combination with cytarabine, mitoxantrone, and etoposide in patients with AML. One study reported an improved efficacy and higher frequency of complete response (29%) compared to traditional response rates [144], and these results were supported by a separate study that reported a complete response rate of 26% in AML patients receiving the same combination of drugs [145]. Despite these positive results, it was also reported that excessive neurological side effects occur at doses higher than 10 mg/kg [146], and owing to a combination of poor response rates and excessive adverse reactions, one clinical trial was terminated prematurely [147].

Several newer “third-generation” compounds have been designed to specifically inhibit the function of P-gp. One agent known as *tariquidar* (XR9576) finds its mode of action in a noncompetitive mechanism, binding to P-gp at a site alternative to that of the transport substrate [148]. This compound is characterized by a greater selectivity toward P-gp and a slower dissociation rate from the protein. *In vitro* assessment of the agent suggested that P-gp inhibition may last up to 22 h after the drug is removed from cells [149]. Despite this high selectivity and potency, it was reported that tariquidar possessed limited clinical efficacy when used in combination with the anthracyclines and taxanes in patients with drug-resistant, advanced breast carcinoma [150].

Another third-generation P-gp inhibitor is LY335979. This agent shows no inhibition of BCRP or MRP1 and unlike tariquidar, competes with other P-gp substrates for binding at the substrate binding site [151,152]. Initial phase I clinical trials in patients with advanced malignancies reported several dose-limiting adverse reactions including neurotoxicity, cerebral dysfunction, hallucinations, and palinopsia [153]. A later study reported that a 640 mg/m² dose of LY335979 could be safely administered over 48 h intravenously. This study assessed the efficacy of the compound in combination with doxorubicin and reported that no dose-limiting side effects occurred [154]. Similarly, during a phase II clinical trial in patients with untreated nonHodgkin’s lymphoma, LY335979 was safely administered over a 24-h schedule without enhancement of cytotoxic related toxicities [155].

5.7 TRANSCRIPTIONAL REGULATION OF THE ABC GENES

In keeping with the focus of this chapter, the transcriptional regulation of *ABCB1*, *ABCC1*, and *ABCG2* in response to the presence of small molecules is discussed. It is important to remember, however, that with many of the ABC proteins having alternative physiological functions and cellular/organ locations, their transcriptional regulation may be induced and maintained by molecular mechanisms not discussed in this chapter.

The constitutive expression of each ABC drug transport protein is dictated by a complex network of transcription factors that interact with each other and response

elements within ABC gene promoter regions. Each of the ABC genes identified to date contains TATA-less promoter regions and possesses initiator elements to which various transcription factors bind before the recruitment of RNA polymerase II [156]. The *ABCB1* gene is known to possess an initiator sequence -6 to $+11$ nucleotides surrounding the transcription start site [157] as well as an inverted CCAAT box (-79 to -75) and a GC-rich element (-56 to -43). The latter two DNA sequence regions are among the most common polymerase II promoter elements and interact with the transcription factors NF-Y and Sp1/Sp3, respectively [158,159]. An additional GC element is known to reside upstream within the promoter region (-110 to -103) that does not interact with Sp1 but may interact with another member of the Sp transcription factor family.

Like *ABCB1*, GC-rich sequences play a vital role in the recruitment of the transcription machinery to the *ABCC1* and *ABCG2* genes. In the case of *ABCC1*, CG elements that lie -91 to $+103$ nucleotides adjacent to the transcription start site have been shown to interact with Sp1 [160], while in the case of *ABCG2*, several potential Sp1 sites were identified within sequences 300 bp upstream of the transcription start site [161]. There are several proteins that have been reported to interact with response elements within the ABC gene promoter regions to either induce or suppress transcription of the ABC drug transporters. These include p53, Ras/Raf, AP-1, and the Wilms' tumor suppressor protein [162]. Of greatest relevance to the pharmacology of small molecules, however, is the overexpression of the ABC drug transport proteins in response to drug exposure.

Several nuclear receptors, including steroid and xenobiotic receptor (SXR), retinoic acid receptor (RAR), farnesoid receptor (FXR), and constitutive androstane receptor (CAR), are known to influence transcription of the ABC genes in response to various xenobiotics [162]. SXR [also known as *pregnane X receptor* (PXR) in rodents, PAR and NR1I2] is activated by a range of small molecules. Xenobiotic detection and subsequent activation of the nuclear receptor involves a large and flexible hydrophobic pocket that resides in the N-terminal LBD. The PXR ligand binding cavity, unlike that of other nuclear receptors, senses a large range of molecules, serving a general protection mechanism against toxic substances [163]. Following activation, the nuclear receptor forms a heterodimer with the retinoid X receptor α (RXR α). This interaction, which is believed to be facilitated by two activation factor domains that lie within the LBD [164], is common among all nuclear receptors involved in the transcriptional regulation of the ABC drug transporters and precedes binding of the heterodimer to response elements within the promoter region of the ABC genes [164]. Binding of the heterodimer to DNA is mediated by a highly conserved region known as the *DNA-binding domain* (DBD). Both the PXR–RXR α and CAR–RXR α heterodimers can bind to the same response elements within the enhancer regions of the *ABCB1* promoter.

5.8 POLYMORPHISMS—EFFECT ON GENE EXPRESSION AND PROTEIN FUNCTION

5.8.1 Polymorphisms in ABC Transport Protein Genes

The growing desire for therapeutics tailored to the individual has, in recent years, stimulated much research into determining the effect of polymorphisms on the function and

transcriptional regulation of the ABC transport proteins. SNPs, which make up over 90% of all genetic mutations, are believed to contribute significantly to the interindividual differences of drug response [165]. This is often revealed through diminished drug efficacy and increased adverse reactions.

SNPs, which are defined as *single nucleotide variations* that exist in 0.1% of the population or greater, may be classified as synonymous or nonsynonymous. Synonymous SNPs are those that do not influence the tertiary structure of the protein but may play a role in the transcriptional regulation of the gene in which it resides. Nonsynonymous SNPs, on the other hand, produce an amino acid change in the protein sequence and hence may affect protein function, interaction with other proteins, or even folding of the tertiary structure. Predicting associations between SNPs and a particular disease, drug response, protein structure or function is made difficult by the number of SNPs believed to exist throughout the genome. This number is rapidly growing, and currently, over 6900 SNPs have been reported in 12 of the major ABC genes [166]. Owing to a phenomenon in which alleles in close proximity are often inherited together, strong correlations may be identified in the expression of minor alleles of different genomic regions. Termed *linkage disequilibrium* (LD), this redundancy of polymorphisms may be exploited in various ways to permit efficient detection of potentially functional SNPs and determine their association with disease and protein function [167].

One method that is commonly adopted in SNP association studies is the selection of a smaller proportion of SNPs, known as *tagging SNPs* (tSNPs), to represent most of the genetic variation within a particular region of interest [167,168]. These tSNPs must not only be in LD but it must also be assumed that no chromosomal recombination has occurred within the region to disrupt the SNP haplotype that would otherwise exist. tSNPs may be selected based on known haplotype distribution or pairwise r^2 LD, the latter being used primarily to select SNPs that best represent different LD blocks within a gene [167,169]. While each method has been shown to select tSNPs with similar predictive power, studies aimed at comparing the effectiveness of each technique suggest those based on haplotype information are most efficient, allowing fewer SNPs to be selected for the same predictive power [169]. Selection of tSNPs may not, however, represent other SNPs in regions of low LD. Similarly, an SNP in a genomic region that is under recent positive selection pressure is generally observed at a higher frequency and is rarely represented by other SNPs in the same region because of differences in ancestral history [166].

Signatures of recent positive selection have been implicated to permit the prediction of potentially functional SNPs. The SNP alleles e22/2677 T (rs2032582) and e27/3435 T (rs1045642) within the *ABCB1* (*MDR1*) gene were previously associated with various functional differences and differences in drug response/other phenotypes and were found to display signatures of recent positive selection in the Chinese population [170,171]. These two positively selected *ABCB1* SNP alleles were found to protect Chinese but not Caucasian men from late-onset (> 60 years) Parkinson's disease [172–174]. The signature of recent positive selection was later employed to demonstrate the feasibility of identifying a previously unknown potentially functionally significant SNP at the *ABCC1* gene locus [175]. The major G allele of SNP 5'UR/G-260C (rs504348) at the promoter region of the *ABCC1* gene was found to be under recent positive selection and to mediate lower *ABCC1* promoter activity compared to the C allele [175]. Before the identification of this potentially functionally significant SNP allele at the *ABCC1* gene that is under recent positive selection, researchers have

failed to detect associations between various SNPs at the *ABCC1* gene and functional differences [176–179]. One possible reason for their failure to detect an association between SNPs at the *ABCC* gene locus and functional difference is due to the general low LD observed at the *ABCC1* gene locus and that this potentially functionally significant promoter SNP under recent positive selection at the *ABCC1* gene locus was never examined in any of the studies. Signatures of recent positive selection were then employed to identify 32 SNPs of potential functional significance at 18 ABC gene loci that are known or implicated to transport drugs [171]. As discussed in this study, it may be assumed that positively selected genomic regions have benefitted the survival of the species in recent evolutionary times and hence play an important functional role. In the situation where an induced change to protein function aids survival, the SNP will be maintained within a population, while those SNPs that produce detrimental effects will reduce in frequency [171].

5.8.2 Effect of SNPs on the Function, Structure, and Expression of ABCB1 (P-gp)

The earliest SNPs believed to affect the expression of P-gp were identified using osteosarcoma cells in 1994. Two SNPs in the promoter region of *ABCB1* gene were identified and the 5'UR/T+103G point mutation was found to enhance the promoter activity of *ABCB1* in cells exposed to the anticancer drugs, doxorubicin and vincristine [180]. Since these early discoveries, advances in high throughput DNA sequencing techniques together with the popularity of this gene in the field of pharmacogenetics have seen a substantial number of additional polymorphisms identified. In the latest release of NCBI's SNP database (dbSNP build 130), 62 coding region SNPs were reported at the *ABCB1* locus. Of these SNPs 40 are nonsynonymous; and 22, synonymous. The majority of these SNPs have yet to be genotyped in any major population cohort, and many of the coding region SNPs associated with *ABCB1* are expressed at low frequency in each of the populations assessed HapMap (phase III) (<http://www.hapmap.org/>).

Nonetheless, three high frequency SNPs at the *ABCB1* gene locus, namely, e13/C1236T (rs1128503), e22/G2677T/A (rs2032582), and e27/C3435T (rs1045642), are often found to be in strong LD, having been identified as part of many haplotypes where the minor alleles may be expressed at highly variable frequencies in different populations [170,181–185]. Although a number of studies have drawn correlation between the presence of these SNPs and either drug response or disease progression, it remains difficult to determine which are causative and which are merely inherited with causative SNPs, which is a confounding issue of the haplotype phenomenon. Despite a general consensus that synonymous SNPs play insignificant roles in the function and expression of P-gp, a recent hypothesis has suggested that the minor T allele at the e27/C3435T (rs1045642) locus results in a codon that is rarely used in humans. This rare codon is hypothesized to result in ribosomal stalling during translation, which affects not only the rate of translation but also the chaperone-facilitated protein folding [186,187]. Early studies into the function of the synonymous SNP e27/C3435T (rs1045642) reported its association with decreased duodenal expression of P-gp and subsequent increase in the plasma levels of the cardiac glycoside digoxin [188]. However, these results could not be replicated by other studies that found either no influence on mRNA expression [189] or an increased expression of the protein in the

duodenum [190]. In a similar fashion, the influence this SNP has on drug activity is controversial. While expression of the minor e27/3435 C allele was correlated with increased efflux of the P-gp substrate, rhodamine 123 [191], it was associated with reduced efflux of nelfinavir [192] and no effect on fexofenadine efflux [193]. A few reports have implicated the wild-type e27/3435 C allele on drug response. Plasma levels of atazanavir, for example, were determined to be higher in HIV patients expressing the CC genotype [194], while the same genotype was linked to a greater incidence of steroid side effects in kidney transplant patients compared to the TT minor allele genotype [195].

Evidence regarding the influence of the nonsynonymous SNP e22/G2677T/A (rs2032582) on the function of P-gp is equally inconclusive. Again, many of the studies exploring the influence of this SNP on *in vivo* P-gp function have assessed this SNP in combination with other SNPs as a haplotype. Functional validation conducted *in vitro* has shown that expression of Ala893, which is produced by the minor 2677 T allele, was found to confer a reduced level of digoxin efflux compared to cells expressing the Ser893 variant [182]. This finding supported an *in vivo* assessment of fexofenadine disposition, where a reduced oral bioavailability of the drug was associated with expression of Ser893, suggesting an enhancement of P-gp activity. It was, however, noted that in most of these studies, the E22/G2677T/A (rs2032582) SNP was studied together with the E27/C3435T (rs1045642) SNP as a haplotype, making it difficult to determine which SNP exerts the greatest influence [182]. The 2677TT/3435CC genotype combination was also associated with lower plasma concentrations of fexofenadine compared to other genotype combinations involving these SNPs [196], while the 2677TT genotype was positively correlated with a higher risk of CsA failure in steroid-resistant ulcerative colitis [197]. e22/G2677T/A (rs2032582) SNP was also positively correlated to tacrolimus neurotoxicity [198], increased resistance to antiepileptic drugs [199], and increased response to cytarabine in AML patients [200]. Curiously, some studies have found no association between e22/G2677T/A (rs2032582), either individually or in haplotype with other SNPs, and drug response [185,201]. For example, e22/G2677T/A (rs2032582) did not influence plasma trough concentrations of ritonavir in HIV patients [202], rhodamine 123 efflux in peripheral blood lymphocytes [203], tacrolimus pharmacokinetics in renal transplant patients [204], or blood, semen and saliva concentrations of ritonavir or lopinavir in HIV patients [205].

The third coding SNP that occurs at highly variable frequencies in different populations and in strong LD with the e22/G2677T/A (rs2032582) and e27/C3435T (rs1045642) SNPs is the e13/C1236T (rs1128503) SNP. This SNP, being synonymous, does not change the amino acid Gly412. Nonetheless, some studies have indicated that this SNP may influence drug response. Significantly increased exposure to irinotecan was associated with the 1236TT genotype [177], whereas the 1236CC genotype was associated with increased response to temozolomide treatment in glioblastoma patients [206]. Positive correlation has also been drawn between this SNP and patient response to CsA [207] and nelfinavir [192]. Nonetheless, some studies also indicated that this SNP does not influence drug response. For example, response to both lopinavir and ritonavir was shown not to be affected by this SNP in HIV patients [205].

Aside from these three commonly reported SNPs, several other SNPs at the *ABCB1* gene locus have also been implicated in drug response. It has been reported that the SNP e27/T3421A (S1141T) (rs2229107) conferred decreased resistance to daunorubicin

in an *in vitro* setting, while the SNPs e5/C266T (M89T) (rs35810889), e17/T1985C (L662R) (rs35657960), and e17/C2005T (R669C) (rs35023033) all increased resistance to at least two of the drugs studied, which also included doxorubicin, valinomycin, and actinomycin D). In the same study e27/T3322C (W1108R) (rs35730308) reportedly decreased resistance to valinomycin when expressed in haplotype with e17/C2005T [208]. It should be noted, however, that opposing studies indicate that many of the SNPs do not influence P-gp function [209,210].

5.8.3 Effect of SNPs on the Function, Structure, and Expression of ABCC1 (MRP1)

SNPs at the *ABCC1* gene locus were found to be in low LD and high haplotype diversity when ~480 individuals from Chinese, Malay, Indian, European Caucasian, and African-American populations were screened [175]. Despite the large number of exonic SNPs identified in this gene, relatively few have been associated with drug response or disease progression. One SNP, e13/C1684T (rs35605), was reported to influence the pharmacokinetics of the irinotecan metabolites SN-38 and APC. However, it was highlighted that this may be due to alternative causative polymorphisms possibly in other membrane transporters [211]. Similarly, the SNPs e2/C218T (T73I) (rs41494447) and e23/G3173A (R1058Q) (rs41410450) were implicated in reduced resistance to at least one of the several drugs including daunorubicin, doxorubicin, etoposide, vinblastine, or vincristine in HEK293 and CHO-K1 cells. In the case of e17/G2168A (R723Q) (rs4148356), the SNP was found to confer reduced resistance to all drugs examined, while e2/G128C (C43S) (rs41395947) did not influence the efficacy of any agent [212]. Additional SNPs influencing the function of MRP1 include the SNP e28/G4009A (A1337T) (rs28364006) that was reported to influence the efficacy of methotrexate together with the intronic SNPs I22/G-1960A (rs2238476) and I9/T-176 C (rs35592) [213]. The e10/G1299T (rs60782127) polymorphism, which confers the amino acid exchange R443S, reportedly increased doxorubicin resistance while decreasing the transport of a number of organic anions [214]. Furthermore, the e2/G128C (C43S) (rs41395947) polymorphism, which was discovered not to influence protein expression or stability [215], was found to disrupt protein localization to the plasma membrane. Association between this SNP and reduced resistance to doxorubicin has also been highlighted [216]. In contrast to these positive associations, the results of a study that assessed the functional significance of 10 nonsynonymous SNPs in HEK293T cells reported that none altered the expression levels of MRP1 or have any impact on protein synthesis or stability [215].

5.8.4 Effect of SNPs on the Function, Structure and Expression of ABCG2

Although several SNPs have been identified in the *ABCG2* gene, few have been characterized and shown to influence the drug transport activity of the protein. One well-characterized nonsynonymous SNP, e5/C421A (Q141K) (rs2231142), is located between Walker A and signature motif C in the NBD. This SNP is associated with a less stable BCRP that is susceptible to proteasomal degradation and diminished localization to the plasma membrane [217]. This SNP was shown to reduce ATPase activity in HEK-293 cells, which was accompanied by a reduced mitoxantrone efflux [218]. An independent study also implicated e5/C421A (Q141K) (rs2231142) in drug

response after reporting an association between the heterozygous variant of the SNP and the onset of diarrhea following gefitinib treatment. Interestingly, however, there was no association in the same cohort with skin toxicity, another common side effect of gefitinib exposure [219]. The same SNP has been implicated in the pharmacokinetics of diflomotecan [220], imatinib [221], atorvastatin and rosuvastatin [222], and methotrexate [213]. SNP e5/C421A (Q141K) (rs2231142) was found not to affect the pharmacokinetics of the camptothecin analog, irinotecan [223] or the drug, lamivudine [200]. Two other nonsynonymous SNPs (V12M and Q126X) at the *ABCG2* gene locus also did not affect pharmacokinetics of the drug lamivudine [200].

5.8.5 Effect of SNPs in Other ABC Proteins

As previously mentioned, potentially functional SNPs have been reported in 12 ABC genes, with several of these associated with drug resistance or disease progression. A synonymous SNP, e15/C2127T (rs908832), found in the *ABCA2* gene was associated with early onset of Alzheimer's disease [224], while a nonsynonymous SNP in the *ABCB11* gene, e13/T1331C (rs2287622), was associated with altered canalicular expression of the protein leading to cholestasis [225,226]. Also, within the *ABCB11* gene, e28/G236A (rs473351), was found to be associated with intrahepatic cholestasis of pregnancy [227]. A few SNPs at the *ABCC2* gene locus have been associated with a defined phenotype including e10/G1249A (rs2273697), which was correlated to *ABCC2* mRNA expression in preterm babies but not in the human placenta [228], and e1/C-24T (rs717620), which was associated with *ABCC2* mRNA levels in normal kidney cortex [229] as well as alterations to the pharmacokinetics of methotrexate in pediatric ALL patients [230]. Similarly, the SNP e10/C1446G was associated with alterations to hepatic expression of MRP2 [231], while the SNPs e18/C2366T (rs56220353) and e31/G4348A (rs56296335) were correlated to both expression level and membrane localization of MRP2 in a kidney cell line [232]. The SNP -5'UR/C211T, which resides in the *ABCC3* gene, was found to be associated with *ABCC3* mRNA levels in human liver tissue [233], yet does not affect mRNA levels in ALL patients [234]. Similar associations were reported for two SNPs located in the *ABCC6* gene, with e24/C3421T (rs72653706) being correlated with a higher susceptibility to early cardiovascular disease [235] and the nonsynonymous SNP E27/G3803A (rs2238472) associated with plasma levels [236]. The final ABC gene to contain an SNP with reported associations to an established phenotypic property is *ABCC11*. SNP e5/G538A (rs17822931) at the *ABCC11* gene locus was found to be associated with earwax type [237].

5.8.6 Diseases Arising from ABC Gene Mutations

Several familial diseases are known to arise from loss-of-function mutations in ABC transporter genes (Table 5.3). Diseases have been associated with each subclass of ABC, with the exception of ABCE and ABCF, which are not associated with active substrate transport.

Familial high density lipoprotein (HDL) deficiency, a genetic disorder transmitted as a dominant trait, and the rarer autosomal recessive disease, but clinically similar, Tangier's disease are associated with defective *ABCA1* [238]. These diseases result

TABLE 5.3 Diseases Associated with Mutations in Genes Encoding Members of the ABC Superfamily

Disease	Associated ABC Transporter	References
Tangier disease, high density lipoprotein deficiency	ABCA1	238,239
Stargardt disease and age-related macular degeneration	ABCA4	4,240
PFIC	ABCB11 (PFIC-II) ABCB4 (PFIC-III)	241,242
Immune deficiency	ABCB2, ABCB3	2
Sideroblastic anemia with ataxia	ABCB7	243
Dubin–Johnson syndrome	ABCC2	244
Pseudoxanthoma elasticum	ABCC6	245
Cystic fibrosis	ABCC7	246,247
PHHI	ABCC8, ABCC9	248
X-linked adrenoleukodystrophy	ABCD1	9
Sitosterolemia	ABCG5, ABCG8	249

Source: Adapted from Ref. 2.

from loss-of-function mutations, of which, over 50 different mutations have been identified within the *ABCA1* gene [239]. Both diseases are characterized by a complete absence of HDL in the blood plasma and subsequently an increased incidence of cardiovascular disease [238,239]. Similarly, various macular disorders, such as Stargardt's disease and age-related macular dystrophy, are linked to mutations in the *ABCA4* gene. This gene encodes the ABCR protein, which is exclusively expressed in photoreceptors and involved in the transport of vitamin A derivatives into the retinal pigment epithelium (RPE) [4]. Degeneration of rods and cones is the ultimate result of expressing loss-of-function mutations in *ABCA4* [240].

As previously highlighted, SNP mutations in *ABCB11* have been associated with the onset of cholestasis; however, it is important to note that mutations in *ABCB4* also contribute to the disease in a similar fashion. Mutations in *ABCB4* and *ABCB11* have been found to cause progressive familial intrahepatic cholestasis (PFIC) types III and II, respectively [241]. Cholestasis, which is characterized by a retention of bile salts in the liver, an absence of biliary phospholipids and elevated bile acid levels in blood plasma ultimately leads to liver failure and, without transplant, patient death [241]. In each disease, mutations in the responsible proteins produce a dysfunctional protein or a phenotype completely lacking detectable protein. This was observed in a screen of 50 PFIC3 patient samples, where ~30 different mutations were observed in the *ABCB4* gene. In this case, no ABCB4 protein was detected following immunostaining of the samples from liver failure patients and this lack of detectable protein was proposed to result from the presence of a premature stop codon and subsequent degradation of mRNA [242,250,251]. In other examples, missense mutations at the Walker A and Walker B motifs of the *ABCB4* gene locus were observed, which prevented ATP binding and hydrolysis [242,250].

One of the most prominent diseases associated with the ABC proteins is CF, which results from mutations in the gene known as *cystic fibrosis transmembrane regulator*

(*CFTR*) or *ABCC7*. Characterized by profuse mucosal secretions within the lungs and an increased vulnerability to bacterial infections, CF continues to be associated with an average life span in patients of just 34 years [246]. Although there have been over 1000 disease-associated mutations described in the *CFTR* gene, there are several that are consistently found in large proportions of CF patients [247]. The most common mutation, known as $\Delta F508$, is present in over 90% of CF patients in the United States and produces a protein lacking a phenylalanine residue at position 508 [247]. Three-dimensional modeling of the *CFTR* protein highlights the importance of this residue in facilitating an interaction in the tertiary structure between the surface of NBD1 and the cytoplasmic loop CS4 in the C-terminal TMD (TMD2) [252]. Despite the defective protein retaining its chloride channel function in cell-free *in vitro* studies, *in vivo* studies revealed that the $\Delta F508$ mutation resulted in a misfolded protein that is swiftly degraded before it localizes to the plasma membrane [247].

From the ABCG family, it has been established that deficiency in functional ABCG5 and ABCG8 proteins produces the autosomal recessively inherited disease, sitosterolemia. This is a rare disease with only 45 cases reported in the literature worldwide and produces significantly elevated levels of plant sterols in the blood plasma. While a healthy individual retains only 5% of the plant sterols consumed in a regular diet, sitosterolemia patients retain 10–25 times more, which ultimately produces coronary and aortic atherosclerosis leading to cardiac arrest [249].

5.9 CONCLUSIONS AND FUTURE PERSPECTIVES

MDR is a problem that diminishes the efficacy of chemotherapy in a range of diseases. It continues to hamper the development of new drugs and also prevents the optimization of new combinations of existing therapies. MDR may be intrinsic to some cell types or acquired following extended exposure to chemotherapy and most often results from a complex network of mechanisms that include drug metabolism, drug efflux, and alterations to the drug target. Despite often conflicting evidence on the role of the ABC transport proteins in clinical MDR, it is clear from decades of research that the ABC transport proteins contribute significantly to this phenomenon.

With the limited success in modulating or inhibiting the function of the ABC transport proteins, it can be argued that this family of proteins has failed as a therapeutic target. Although only meant as adjuvant therapies, the existing ABC transport protein modulators and inhibitors have proven ineffective in reversing MDR and continue to be associated with high toxicities at dose concentrations required to effectively inhibit the target protein. That said, to develop agents that improve existing chemotherapy regimens and diminish the effects of MDR, the ABC transport proteins must be targeted. Molecular mechanisms of inhibition such as RNA interference may prove more effective than small-molecule treatment. However, many ABC transporters are ubiquitously expressed and play an important physiological role. Hence, the specificity of any modulator or inhibitor must be improved in order to reduce the onset of adverse effects.

Attempts to develop novel strategies to counteract the effects of MDR will undoubtedly benefit from the recent interest in the pharmacogenomics of the ABC drug transporters. With growing evidence to suggest that interindividual differences in response to therapy are linked to the presence of SNPs in the coding and promoter regions of the

ABC genes and their protein regulators, it is clear that a better understanding in this field will permit chemotherapy protocols to be better tailored to individual populations.

6.1 INTRODUCTION

Xenobiotic transporters are increasingly scrutinized for their contribution to the sub-optimal pharmacokinetics (PK) and safety of drug candidates that fail in clinical trials. Over the last decade, pharmaceutical industry has used structure–activity relationships (SARs) to develop compounds with half-lives conducive to no more than once-a-day dosing and a lower incidence of metabolism-based drug–drug interactions (DDIs), yet

unexpected drug interactions were encountered in the clinic. Several of these interactions have now been attributed to drug transporters. We now know that higher metabolic stability often results in the unpredictable involvement of drug transporters, leading to transporter-mediated drug interactions. Any significant changes in transporter expression and function can contribute to variable PK, unexpected toxicities, and drug interactions.

DDIs involving membrane transporters can be the result of competition for the same substrate-binding site, tight or allosteric binding leading to inhibition of transporter activity, or changes in transporter expression. These interactions could alter the blood-concentration-time profiles of drugs, leading to altered levels of a coadministered compound. Evaluating the substrate potential of a drug candidate for specific transporters *in vitro* is beneficial, especially when the organ is also the drug target. For example, the hepatitis C drugs, α -interferon and S-acyl-2-thioethyl esters, or the HMG-CoA inhibitors, such as the statins, must achieve adequate concentrations in the liver for pharmacological activity. Inhibition of transporter activity could result in changes to hepatic availability of xenobiotics. Transporters can also play a role in toxicities, as inhibition of transporter activity could lead to increased drug concentrations or inhibition clearance (CL) of endogenous substrates, for example, bile salts, leading to cholestasis.

The solute carrier (SLC) transporter family includes over 300 membrane-bound transporters that comprise 55 gene families and at least 362 putatively functional protein-coding genes. These transporters control the uptake of endogenous compounds and xenobiotics including sugars, amino acids, nucleotides, inorganic ions, and drugs, in all living cells. According to their mode of action, as depicted in Fig. 6.1, SLC transporters can be divided into passive (facilitated) and active transporters (symporters and antiporters). Passive transporters allow the passage of solutes across membranes down their electrochemical gradients, and active transporters create ion/solute gradients across membranes, utilizing diverse energy-coupling mechanisms. While symporters transport the two moieties across the membrane in the same direction, antiporters exchange these in opposite directions.

Figure 6.1 Schematic of membrane topology for SLC transporters, based on predicted structure of OAT.

SLC transporters are located in all cellular and organelle membranes, with the exception of the nuclear membrane. Substrates of SLC membrane proteins include endogenous substances such as amino acids, glucose, inorganic cations and anions, bile salts, carboxylate, essential metals, biogenic amines, neurotransmitters, vitamins, fatty acids, lipids, nucleosides, hormones, urea, and xenobiotics. These transporters are therefore essential for the normal functioning of cells and organ systems.

Less than 20 of the known membrane-bound transporters have been characterized as relevant to drug-related interactions. These participate in the absorption, disposition, and/or excretion of drugs, xenobiotics, and endogenous compounds in organs including the intestine, liver and/or kidney, and brain and perform homeostatic functions. The families of SLC transporters related to drug transport are SLCO, SLC1A10, SLC47, SLC1A22, and SLC1A7 and are discussed in details in this review. Of the six SLCO gene families, four transport organic anion-transporting polypeptides (OATPs) are most relevant to drug transport. These transporters form a superfamily of sodium-independent transport systems that facilitate the transmembrane transport of amphipathic, endogenous, and exogenous organic compounds. Among this class, SLCO1 family is the best characterized and includes OATP1B1, 1B3, and 2B1. SLCO5 and SLCO6 are also believed to be important in drug transport. The SLC10 family participates in bile salt transport and has two well-characterized members in humans: the Na^+ /taurocholate-cotransporting polypeptide (NTCP) and the apical Na^+ -dependent bile salt transporter (ASBT), which are critical to the enterohepatic recirculation of bile salts, along with efflux transporter bile salt export pump (BSEP) on the canalicular member of hepatocytes. NTCP and ASBT are cotransporters that mediate sodium-dependent, electrogenic uptake of mainly bile salts into hepatocytes (NTCP), biliary epithelial cells, ileal enterocytes, and renal proximal tubular cells (ASBT). SLC47 includes the multidrug and toxicant extrusion-1 and -2 genes (MATE1 and MATE2). SLC1A22 is the major facilitator superfamily and includes organic cation transporters (OCTs), zwitterion/cation transporters (OCTNs), and organic anion transporters (OATs). Transporters of the SLC22 family function as uniporters that mediate facilitated diffusion in either direction (OCTs), anion exchange (OAT1 and OAT3) and Na^+ /l-carnitine cotransport (OCTN2), and play an important role in the detoxification of exogenous compounds. SLC7, with 14 members, represents cationic amino acid and glycoprotein transporters. This family is divided into two subgroups, the cationic amino acid transporters and the glycoprotein-associated amino acid transporters, also called *light chains* or *catalytic chains* of the hetero(di)meric amino acid transporters.

The interplay between chemicals and transporters is evaluated using multiple *in vitro* and *in vivo* experimental approaches. For *in vitro* evaluations, the method of choice has been stably transfected cell lines. The cell lines most commonly used for transporter transfections are the MDCK, HEK-293, and LLC-PK1, and in most cases, singly transfected cell lines suffice. To evaluate hepatic transport, fresh or cryopreserved primary hepatocytes provide a good model of hepatic uptake, efflux, biliary excretion, transporter-mediated drug interactions, induction, and hepatotoxicity. *In vivo*, transgenic rodents have been used to study drug transport, for example, the oatp2 and oatp4 single-knockout mice and the oct1/oct2 double-knockout mice.

Since transporters are widely distributed and have a broad substrate spectrum, altered transport kinetics due to the functional consequences of genetic variations (polymorphisms) can contribute to the interindividual variability of drug PK and pharmacodynamic (PD) effects, as well as to idiosyncratic toxicities. Owing to this, evaluations

of the effects of polymorphisms on ADME (absorption, metabolism, distribution, and elimination) should also be evaluated.

6.2 NOMENCLATURE AND GENERAL STRUCTURE OF SLC TRANSPORTERS INVOLVED IN XENOBIOTIC TRANSPORT

The SLC superfamily comprises more than 360 putatively functional protein-coding genes organized into 55 SLC families on the basis of alignment similarities and differences in transport mechanisms [1]. A website maintained by the HUGO Gene Nomenclature Committee provides the latest updates of SLC transporter nomenclature (<http://www.genenames.org/genefamily/SLC.php>). Generally, the root symbol of SLC is used to name the genes followed by a number or letter and then another number denoting the isoform, for example, SLC22 represents SLC family 22. The letters, A–E are used to specify subfamilies (Table 6.1). Owing to the new isoforms discovered within a given species and the rapid evolution of this family, the initial naming system underwent modifications to accommodate a unique, species-independent classification. For example, in the subclass originally named SLC21 that encodes OATP, the numeral “21” and the letter “A” were replaced by the letter “O,” which stands for organic transporter [1]. It is also commonly accepted in transporter nomenclature that upper case letters denote the human protein, that is, OATP/SLCO and lower case letters indicate transporter proteins of preclinical species, for example, Oatp/Slco.

TABLE 6.1 Major Human SLC Transport Proteins Involved in ADME

Transporter Symbol	Transporter Name	Synonyms	Chromosome
SLC7A5	Solute carrier family 7 (amino acid transporter light chain, L system), member 5	LAT1, E16, D16S469E, MPE16, CD98	16q24.3
SLC7A5P1	Solute carrier family 7 (amino acid transporter light chain, L system), member 5 pseudogene 1	LAT1-3TM, MLAS	16p11.2
SLC10A1	Solute carrier family 10 (sodium/bile acid cotransporter family), member 1	NTCP	14q24
SLC10A2	Solute carrier family 10 (sodium/bile acid cotransporter family), member 2	ASBT, ISBT	13q33
SLC15A1	Solute carrier family 15 (oligopeptide transporter), member 1	PEPT1, HPECT1, HPEPT1	13q33-q34
SLC15A2	Solute carrier family 15 (H ⁺ /peptide transporter), member 2	PEPT2	3q21.1
SLC16A1	Solute carrier family 16, member 1 (monocarboxylic acid transporter 1)	MCT, MCT1	1p12
SLC16A7	Solute carrier family 16, member 7 (monocarboxylic acid transporter 2)	MCT2	12q13
SLC22A1	Solute carrier family 22 (organic cation transporter), member 1	OCT1	6q25.3

TABLE 6.1 (*continued*)

Transporter Symbol	Transporter Name	Synonyms	Chromosome
SLC22A2	Solute carrier family 22 (organic cation transporter), member 2	OCT2	6q25.3
SLC22A3	Solute carrier family 22 (extraneuronal monoamine transporter), member 3	OCT3, EMT	6q25.3
SLC22A4	Solute carrier family 22 (organic cation/ergothioneine transporter), member 4	OCTN1, MGC34546	5q23.3
SLC22A5	Solute carrier family 22 (organic cation/carnitine transporter), member 5	OCTN2, SCD	5q23.3
SLC22A6	Solute carrier family 22 (organic anion transporter), member 6	ROAT1, PAHT, OAT1	11q12.3
SLC22A7	Solute carrier family 22 (organic anion transporter), member 7	NLT, OAT2	6p21.1
SLC22A8	Solute carrier family 22 (organic anion transporter), member 8	OAT3	11q12.3
SLC22A9	Solute carrier family 22 (organic anion transporter), member 9	OAT4, FLJ23666, UST3, OAT7	11q12.3
SLC47A2	Solute carrier family 47, member 2	FLJ31196, MATE2, MATE2-K	17p11.2
SLC28A1	Solute carrier family 28 (sodium-coupled nucleoside transporter), member 1	CNT1	15q25.3
SLC28A2	Solute carrier family 28 (sodium-coupled nucleoside transporter), member 2	CNT2, SPNT1, HCNT2, HsT17153	15q15
SLC28A3	Solute carrier family 28 (sodium-coupled nucleoside transporter), member 3	CNT3	9q21.33
SLC29A1	Solute carrier family 29 (nucleoside transporters), member 1	ENT1	6p21.1
SLC29A2	Solute carrier family 29 (nucleoside transporters), member 2	DER12	11q13
SLC29A3	Solute carrier family 29 (nucleoside transporters), member 3	ENT3, FLJ11160	10q22.2
SLCO1A2	Solute carrier organic anion transporter family, member 1A2	OATP, OATP1A2, OATP-A	12p12
SLCO1B1	Solute carrier organic anion transporter family, member 1B1	OATP-C, LST-1, OATP1B1	12p12
SLCO1B3	Solute carrier organic anion transporter family, member 1B3	OATP8, OATP1B3	12p12
SLCO2B1	Solute carrier organic anion transporter family, member 2B1	OATP-B, OATP2B1	11q13

Figure 6.2 Schematic depicting passive and active transport processes of SLC transporters.

Figure 6.3 Depiction of the carrier-mediated facilitated transport processes for transporters such as OCT.

The SLC family consists of proteins containing multiple transmembrane domains (Fig. 6.1) and facilitates the movement of a substrate across cellular membranes, either along or against its concentration gradient. Based on the transporting mechanism, the SLC superfamily is categorized into passive (uniporters or facilitative transporters) and secondary active transporters (Fig. 6.2). Passive transporters, also known as *facilitated transporters*, utilize an electrochemical potential difference caused by the respective substrates to move substrates down a concentration gradient (Fig. 6.3). In contrast, secondary active transporters translocate the substrates uphill against their electrochemical gradient by coupling with another ion or molecule that flows downhill with its concentration gradient (Fig. 6.4). Basically, these processes are free-energy changes. The secondary active transporter families, including the OATPs (SLC21A or OATP), peptide transporters (SLC15A or PEPT), novel-type OCT (SLC22A or OCTN), and

Figure 6.4 Depiction of carrier-mediated active transport processes for transporters such as OAT.

sodium-dependent bile acid transporter (SLC10A1 or NTCP), either utilize ion gradients across membranes or cotransport with intracellular and/extracellular ions [2,3] (Fig. 6.4). On the basis of the direction of the coupling ion or molecule, the secondary active transporters are further categorized as symporters and antiporters (Fig. 6.2). Symporters move the transported molecule and coupled ion toward the same direction, while antiporters move the molecules and coupled ion in opposite directions. In addition to localization at the cellular plasma membranes, the SLC proteins are also expressed on membranes of cellular organelles such as mitochondria, endoplasmic reticulum, Golgi, and other vesicles. These SLC transporters are termed *mitochondrial* and *vesicular transporters* [1] and are not discussed in this chapter.

Relatively few of the SLC transporters have been established to be actively involved in disposition of market drugs or drug candidates. From a pharmaceutical industry perspective, these SLC transporters are of great importance, in that they may rate-limit drug exposure to metabolizing enzymes in metabolic tissues, thus serving as gatekeepers for drug disposition and as drug targets, facilitating drug delivery and being responsible for drug interactions. For example, the glucose and neurotransmitter transporters have been exploited as drug targets for the past two decades, and more recently, the oligopeptide transporter (PEPT1) is being investigated as an endogenous delivery mechanism for drugs, where translocation across the intestinal mucosa or blood–brain barrier (BBB) is challenging [4]. Considerable progress has been made in understanding SLC transporter-mediated DDI and toxicities [5]. In 2010, the International Transporter Consortium summarized several SLC carriers including OATPs/SLCO, OCTs/SLC22, and OATs/SLC22, which are clinically relevant to DDI, and made recommendations for evaluating the substrate and inhibition potential of candidate drugs with these transporters [6]. These transporters are discussed in more details below.

6.3 DISTRIBUTION AND PATHOPHYSIOLOGY OF SLC TRANSPORTERS

The SLC family is distributed in the epithelia of various organs and transports a variety of endogenous and exogenous substrates (Table 6.2). For example, OAT3 is expressed on the basolateral membrane of the proximal tubule in the kidney and mediates the secretion of organic anions into urine via carrier-mediated active transport (Fig. 6.8) [7–9]. To move a substrate across the cell membrane, the SLC transporters need to collaborate with the ATP-binding cassette (ABC) transporters or other SLC transporters in the same or opposite membrane of polarized cells. Recently, the human MATE2-K transporter was identified as a luminal membrane transporter that transports organic cations out of renal proximal tubular cells in coordination with OAT3 [10]. Diverse organ distribution of the SLC transporters and coexistence of multiple transporter isoforms in tissues suggest that collaborative and compensatory functions of transporters might play an important role in physiological communication network between organs, as well as tissue distribution and elimination of xenobiotics. Transporter pharmacology is a rapidly emerging subject in drug discovery and development and therefore is of particular interest to the pharmaceutical industry. The SLC members discussed below are clinically relevant in drug absorption, drug disposition, and/or DDI.

6.3.1 SLCO Superfamily: Organic Anion-Transporting Polypeptides (OATPs)

The SLCO subfamily proteins are predicted to have a 12-transmembrane-domain structure, similar to that depicted in Fig. 6.1. These transporters are expressed in organs such as the intestine, liver, muscle, and BBB. Members of the SLCO family include several OATP transporter isoforms that play an important role in uptake of structurally diverse endogenous compounds and xenobiotics, including clinical therapeutics. OATP transporters are involved in the entry of diverse drugs into organs. The inhibition or downregulation of OATP expression and/or function by a drug, or gene polymorphisms, may lead to PK alterations and an increase in the propensity for DDI [11].

OATP1A2/SLCO1A2 (formerly OATP-A) has been identified in the liver, brain, kidney, and testes [12] and transports diverse compounds, such as steroid sulfates, thyroid hormones, and opioid peptides [13]. In contrast to the distribution of OATP1A2, OATP1B3/SLCO1B3 and OATP1B1/SLCO1B1 are believed to be liver specific (Fig. 6.6) [14]. Immunohistochemical analysis indicates that OATP1B1, also referred to as *liver-specific transporter 1* (LST-1), OATP2, or OATP-C is localized to the basolateral (sinusoidal) membrane of hepatocytes [15]. Generally, OATP transporters exhibit a broad substrate selectivity that overlaps across isoforms. For example, the substrates for OATP1B1 or 1B3 include anionic (e.g., statins such as pravastatin, pitavastatin, and rosuvastatin), zwitterionic (e.g., rifampicin), and neutral lipophilic (e.g., paclitaxel) drugs. OATP1B1 and 1B3 also transport endogenous substances, such as bile acids, thyroid hormones, steroid sulfates, glucuronide conjugates, and peptides [12,16]. Comprehensive lists of human OATP substrates have been published and provide more details [17,18].

OATP2B1/SLCO2B1 (previously OATP-B) was initially cloned from the human brain and subsequently found in the liver, kidney, lung, heart, placenta, and gastrointestinal (GI) tract [19,20]. Functionally, OATP2B1 demonstrates higher transporter activity for estrone-3-sulfate and appears to have more limited substrate specificity relative to OATP1B1 or 1B3 [19].

TABLE 6.2 Major Human SLC Transport Proteins, with Some Known Substrates and Inhibitors

Transporter	Organ, Cell, Membrane	Substrates Used Experimentally	Substrate Drugs	Endogenous Substrates	Inhibitors and Inhibitor Drugs
OATP1B1	Liver, hepatocyte, basolateral membrane	BSP, E3S, E17 β -G	Statins, repaglinide, olmesartan, enalapril, temocaprilat, valsatan	Bile acids, bilirubin, steroid hormones	Rifampicin, rifamycin SV, saquinavir, ritonavir, cyclosporine
OATP1B3	Liver, hepatocyte, basolateral membrane	BSP, cholecystokinin 8, E17 β -G	Statins, fexofenadine, telmisartan, valsartan, paclitaxel, enalapril, erythromycin, phalioidin	Bile acids, steroid hormones	Rifampicin, cyclosporine, ritonavir
OATP2B1	Liver, hepatocyte, basolateral membrane. Endothelia	E3S, BSP	Statins, fexofenadine, glyburide, rifampicin	Bile acids, steroid hormones	Rifampicin, cyclosporine
OATP1A2	Brain capillaries, endothelia. Liver, cholangiocytes. Kidney, distal nephron	E3S, BSP, fexofenadine	Methotrexate ouabain, levofloxacin, statins	Bile acids	Naringin, ritonavir, lopinavir, saquinavir, rifampicin, verapamil, dexamethasone, ketoconazole, lovastatin
OAT1	Kidney, proximal tubule, basolateral membrane. Placenta	PAH	Adefovir, zidovudine, ciprofloxacin, methotrexate	Cyclic nucleotides, prostaglandin, uric acids	Probenecid, novobiocin

(continued overleaf)

TABLE 6.2 (*continued*)

Transporter	Organ, Cell, Membrane	Substrates Used Experimentally	Substrate Drugs	Endogenous Substrates	Inhibitors and Inhibitor Drugs
OAT3	Kidney, proximal tubule, basolateral membrane. Brain, choroid plexus, and blood–brain barrier	E3S, furosemide, bumetanide	NSAIDs, cefaclor, ceftizoxime,	Prostaglandin, uric acids, bile acids; conjugated hormones	Probenecid, novobiocin
OCT2	Brain, capillaries. Endothelia. Liver, cholangiocytes. Kidney, distal nephron	E3S, BSP, dehydroepiandrosterone sulfate	Fexofenadine, methotrexate, digoxin, statins	Bile acids, choline, acetylcholine, and monoamine neurotransmitters	Naringin, ritonavir, rifampicin
OCT1	Liver, hepatocytes, basolateral membrane. Intestine, enterocytes, apical membrane	TEA, MPP	Metformin, oxaliplatin	Choline, acetylcholine, and monoamine neurotransmitters	Quinine, quinidine, disopyramide

MATE1	Kidney, proximal tubular cells, apical membrane. Liver, hepatocytes, apical membrane. Skeletal muscle	TEA, MPP	Metformin, cephalixin, acyclovir, ganciclovir	Peptides and nucleosides	Quinidine, cimetidine, procainamide, verapamil
MATE2-K	Kidney, proximal tubular cells, apical membrane	Metformin, MPP	MPP, TEA	Creatine, guanidine, thiamine	Cimetidine, quinidine, pramipexole
NTCP	Liver, hepatocytes, apical membrane	Bile acids (e.g., taurocholic acid, glycocholic acid)	Rosuvastatin, pitavastatin, atorvastatin	Bile acids, iodothyronines	Troglitazone, bosentan

Abbreviations: BSP, bromosulfophthalein; E3S, estrone-3-sulfate; E17 β -G, estradiol-17 β -glucuronide; PAH, *para*-aminohippurate; TEA, tetraethylammonium; MPP, *N*-methylpyridinium.

6.3.2 SLC22 Superfamily: Organic Anion, Organic Cation, and Zwitterion Transporters (OATs/OCTs/OCTNs/MATEs)

Since Gründemann *et al.* discovered the rat Oct1 in 1994 [21], its orthologs were subsequently identified and found to be expressed in excretory organs such as the kidney. SLC22 transporters play a critical role in maintaining homeostasis of endogenous substances and urinary elimination of therapeutic agents by carrier-mediated facilitated transport (Fig. 6.3). The SLC22 transporters are also expressed in barrier organs such as the choroid plexus, retina, and placenta [22] and contribute to disposition and homeostasis of organic anions and cations, thereby modulating efficacy and toxicity of clinical therapeutics. SLC22 transporters interact with structurally diverse substrates. On the basis of the substrate specificity and mechanism of transport, SLC22 members are divided into several subgroups including OCTs, OATs, OCTNs, unknown soluble transporters (USTs), and fly-like putative transporters (FLIPTs) [23].

6.3.2.1 OAT Subtypes 1–5. The transporters in this group translocate organic anions including xenobiotics, hormones, and biogenic amines against electrical and chemical gradients. OAT1 (SLC22A6) is expressed mainly at the basolateral membrane of proximal tubule cells and mediates the uptake of organic anions such as *p*-aminohippurate (PAH) from blood into renal proximal tubular cells. In *in vitro* functional assays, an outwardly directed concentration gradient of α -ketoglutarate or glutarate can improve the OAT1-mediated PAH transport, suggesting that α -ketoglutarate gradient provides the driving force for the uptake of organic anions [24]. OAT1 is thus identified as an organic anion/dicarboxylate exchanger. OAT2 (SLC22A7) is expressed abundantly on the basolateral membrane of the liver (sinusoidal membrane) and weakly in the kidney, with marked gender-based differences in expression [25]. Unlike OAT1, OAT2 transports substrates without dependence on sodium, dicarboxylate, glutarate, and α -ketoglutarate gradients and is not considered an organic/dicarboxylate exchanger [26]. Oat3 (SLC22A8) was initially cloned from a rat brain cDNA library and subsequently detected in the kidney, brain, liver, and at low concentrations in the eyes [27]. OAT3 is located on the basolateral membrane of the proximal tubule in the kidney and on the apical membrane of the choroid plexus in the brain [28]. Largely overlapping with the substrates of OAT1 and 2, OAT3 is capable of transporting PAH, methotrexate, cimetidine, and estrone sulfate.

Within the OAT family, OAT4 (SLC22A11) is the only transporter highly expressed in both the placenta and the kidney [22]. Expression of the OAT4 protein was confirmed on the apical membrane of the proximal renal tubular cells, but thus far, there is no consensus on its function. Similar to OAT1 and OAT3, OAT4 is reported to be responsible for reabsorption of substrates from the lumen, in exchange for dicarboxylates. The substrate spectrum of OAT4 is relatively narrow as compared with the other OAT isoforms. OAT4 substrates include estrone sulfate, dehydroepiandrosterone sulfate, ochratoxin A, prostaglandin E₂ (PGE₂), and prostaglandin F (PGF) [29].

Through computational analysis of the genome database, Oat5 (Slc22a19) was discovered [30]. The expression of Oat5 in mouse and rat is confirmed, and a human OAT5 ortholog is yet to be identified. Human OAT6 (SLC22A20), OAT7 (SLC22A9), OAT8 (SLC22A25), OAT10 (SLC22A13), FLIPT1 (SLC22A15), and their rat orthologs have been identified by searching genome databases or via PCR homology screening approaches [31–33]. However, the functional characteristics of this so-called orphan

transporter group are yet to be determined. To date, there is no evidence that these transporters play a major role in xenobiotic disposition.

6.3.2.2 OCT Subtypes 1–3. Transporters in this class mainly translocate organic cations and weak bases and are electrogenic, sodium independent, and bidirectional [23]. OCT1 (SLC22A1) is predominantly expressed on the sinusoidal membrane of hepatocytes in human and rat liver and is also present in other preclinical species such as mouse and rabbit [34,35]. It is also found on the basolateral membrane of small intestinal enterocytes and the renal proximal tubular cells. OCT1 mediates Na^+ -independent transport of type I organic cations (protonated molecules), such as tetraethylammonium (TEA), 1-methyl-4-phenylpyridinium (MPP^+), *N*1-methylnicotinamide (NMN), dopamine, and choline [36], as well as type II cations (larger and bulkier cations) including methyl-quinine and quinidine. OCT1-mediated organic cations transport is potential, sensitive, and electrogenic.

OCT2 (SLC22A2) is expressed predominantly in kidney and also in placenta, lung, brain, and small intestine [23]. OCT2 is localized to the basolateral membrane of the distal tubule in the kidney and mediates uptake from the blood to the proximal tubular cells during the renal secretion of organic cations [37]. OCT2 transports many organic cations and plays an important role in the pharmacological, PK, and toxicological properties of therapeutics. In the brain, OCT2 is expressed on the apical (ventricular) membrane in epithelial cells of the choroid plexus. Since OCT2 transports monoamine neurotransmitters including dopamine, noradrenaline, adrenaline, and 5-hydroxytryptamine, tissue-dependent expression of OCT2 in tissues such as neurons, lung, and choroid plexus may participate in the regulation of interstitial and intracellular concentrations of monoamine neurotransmitters and cationic drugs [38].

OCT3 (SLC22A3) has a broader tissue distribution than OCT1 and OCT2 and is also detected in muscle, glial, cardiac, and cancer cell lines. OCT3 is localized on the basolateral membrane of the trophoblast in placenta, the epithelial cells of renal proximal tubules and hepatocytes, and the luminal membrane of bronchial epithelial cells and small intestinal enterocytes [39–41]. The broader distribution of OCT3 contributes to physiological functions such as regulation of the interstitial concentration of monoamine neurotransmitters and cationic drugs in the central nervous system and release of acetylcholine from placenta [42]. The substrate specificity of OCT3 is similar to that of OCT1 or OCT2, which is capable of transporting type I and II organic cations such as the neurotransmitters, namely, adrenaline, TEA, noradrenaline, and histamine, and the neurotoxin MPP^+ .

OCT6 (SLC22A16), also named CT2 or FLIPT2, is located predominantly in human testis but is also found in the embryonic liver, hematopoietic cells, and cancer cell lines. OCT6 transports carnitine with a high affinity and shows a greater selectivity for substrates. For example, OCT6 bidirectionally transports L-carnitine across cell membranes but does not interact with TEA and other organic cations [43].

6.3.2.3 OCTN1–3 (SLC22A4–6). These transporter proteins function as organic cation uniporter or H^+ /organic cation antiporters, or as uniporters for organic cations or Na^+ /carnitine cotransporters. OCTN1 (SLC22A4) is expressed in kidney, muscle, placenta, prostate, and heart [44]. OCTN1 is an electroneutral H^+ /organic cation antiporter and mediates the transport of monovalent organic cations including TEA, quinidine, pyrilamine, verapamil, and the zwitterion carnitine [45]. OCTN1 is expressed on the

luminal membrane of renal proximal tubular cells and mediates the cellular efflux of organic cations. The bidirectional function of this transporter indicates that it participates in reabsorption of organic cations [44]. There are significant species differences in the localization and transport mechanism of OCTN1 that is strongly expressed in the liver of rat, but not in humans [46].

OCTN2 (SLC22A5) is a Na^+ -dependent transporter for TEA, choline, verapamil, pyrilamine, L-carnitine, and the zwitterionic β -lactam antibiotic cephaloridine. It also serves as a Na^+ -independent cation transporter [41], mediating the Na^+ -independent cotransport of short-chain acyl esters of carnitine, zwitterionic β -lactam antibiotics, L-lysine, and L-methionine. In the absence of Na^+ , OCTN2 transports the organic cations and weak bases including quinidine, TEA, pyrilamine, verapamil, and choline [47]. Expression of OCTN2 is relatively ubiquitous and has been confirmed in kidney, muscle, heart, brain, lymphocyte, and sperm [23,46]. In kidney, luminal localization of OCTN2 in the proximal renal tubule provides the active process of reabsorption of L-carnitine, which can contribute to the secretion and reabsorption of organic cations. In the heart and muscles, OCTN2 mediates the uptake of L-carnitine into adipocytes and cardiac myocytes [23]. Polymorphic isoforms of OCTN1 and OCTN2 are linked to inflammatory bowel disease [48]. OCTN3 is found in the mouse testis and kidney and is believed to be less relevant for organic cation transport than OCTN1 and OCTN2.

6.3.2.4 MATE Transporters. MATEs are OCTs with multiple isoforms. MATE1 (SLC47A1) is a human and mouse ortholog of the multidrug and toxin extrusion family conferring multidrug resistance to bacteria [49]. MATE1 is primarily expressed in the liver, kidney, and skeletal muscles and weakly in the heart [50]. Human MATE1 is a Na^+ -independent transporter and transports TEA via a proton-cation antiport process. MATE1 interacts with MPP^+ , serotonin, cimetidine, quinidine, and verapamil, demonstrating functional similarity to the OCTs and OCTNs. MATE1 is localized to the luminal membranes of proximal tubular cells in the kidney and on the canalicular membrane of hepatocytes in the liver and is thought to play a key role in the excretion of organic cations through exchange of protons in the kidney. Recently, MATE1-coordinated transport of antibiotics with OAT3 was reported [10].

MATE2 comprises two splice variants, MATE2-K and MATE2-B. MATE2-K is predominantly expressed in the human kidney, whereas MATE2-B was identified in the human brain. MATE2-K is thought to be the kidney-specific H^+ /organic cation antiporter mediating the luminal efflux of a wide range of cationic compounds (endogenous substrates such as creatine, guanidine, and thiamine and drug substrates such as metformin and oxaliplatin) across the brush border membranes in the renal proximal tubular cells; however, the clear function of human MATE2-B is yet to be determined.

6.4 ROLE OF THE MAJOR SLC TRANSPORTERS IN DIFFERENT ORGANS

As described in the previous section, various drug transporters are expressed in the liver, kidney, intestine, placenta, and BBB. In most cases, individual SLC transporters are preferably expressed on either the apical or the basolateral membrane of polarized cells and work together to mediate the transport of xenobiotics. For example, in the liver, drugs are first taken up through the sinusoidal (basolateral or blood side)

membrane by hepatic uptake transporters. Once inside the cells, these drugs either are metabolized by P450 metabolism (Phase I) and/or conjugation (Phase II) and/or transported out of hepatocytes by transporter proteins located on the canalicular (apical) membrane and subsequently eliminated across bile canaliculi, or are transported back to the blood through sinusoidal (basolateral) transporters. The unidirectional transport process mediated by apical and basolateral membrane transporters guarantees the vectorial elimination of xenobiotics from the body. From a pharmaceutical perspective, organ distribution of SLC transporter proteins that is of the most interest with respect to absorption, disposition, and elimination is described below.

6.4.1 SLC Transporters in Intestine

Multiple parallel transport processes, such as passive transcellular diffusion, carrier-mediated absorption, and carrier-mediated efflux, exist in the intestinal barrier [51,52]. Absorption of therapeutics, nutrients, bile acids, and other compounds in the GI tract is often mediated by SLC transporters expressed in enterocytes (Fig. 6.5) [53]. Uptake transporters including PEPT1, ABST, concentrative or equilibrium nucleoside transporters (CNT1–3/SLC28A1–3 or ENT1–3/SLC29A1–3), OATP family, and organic cation/anion/zwitterion transporters (OAT/OCT/OCTN) facilitate drug absorption across the intestinal brush border membrane. These SLCs are critically involved in absorption, thereby contributing to the distribution and PK characteristics of many drugs. For example, β -lactam antibiotics and dipeptidyl-like anticancer drugs, such as bestatin, are absorbed by PEPT transporters [54,55].

Three subtypes of the SLC22 family have been identified in the GI tract: OCTs, OATs, and the OCTNs. OATPs of the SLCO family also have important functions in the intestine and transport structurally diverse substrates [56]. ASBT is critical for

Figure 6.5 Schematic of apical and basolateral membrane transporters in human enterocytes [50].

enterohepatic circulation of bile acids by mediating their absorption at the apical membranes of enterocytes [57]. A defect in ASBT function could result in primary bile acid malabsorption characterized by congenital diarrhea and reduced plasma cholesterol levels [58]. Nucleoside transporters belonging to the SLC28 family are essential for *de novo* nucleic acid synthesis and for cancer therapy by mediating uptake of anti-cancer and antiviral nucleoside analogs into tumor tissues. CNT1–3 (concentrative) are localized to the apical membranes of epithelial cells and mediate nucleoside uptake against concentration gradients, whereas ENT1–3 (equilibrium) translocate nucleoside substrates following concentration gradients and are believed to be responsible for nucleoside efflux at the basolateral membranes of enterocytes. The oligopeptide transporter PEPT1 is present at the apical membrane of enterocytes and transports nutrient-derived peptides, as well as peptidomimetic drugs [59].

Recently, targeting uptake transporters in the design of poorly absorbed drugs has been proposed as a strategy for improving bioavailability and therapeutic efficacy [4,60]. Because active uptake and efflux transporters in the GI tract may contribute to the bioavailability of orally administered drugs, modulation of their expression levels or activities may lead to potential drug transporter interactions during absorption.

6.4.2 SLC Transporters in Liver

Hepatic drug elimination generally constitutes a series of events including (i) transport of drug into the hepatocyte via passive diffusion or hepatic uptake transporters (phase 0); (ii) intracellular metabolism, including cytochrome P450 metabolism (phase I) and/or conjugation (phase II); and (iii) flux into blood or bile via the hepatic transporters (phase III). Recently, the role of hepatic SLC uptake transporters in drug disposition has received considerable attention [6], as these proteins play an important role in translocating endogenous compounds and drugs from blood into the liver. This function represents a rate-limiting step in the entry of substrates into hepatocytes and plays a key role in drug elimination, even for the compounds that are primarily metabolized by hepatic enzymes. The distribution and elimination of drugs in the liver is dependent on the degree of expression of each transporter protein and substrate affinity for a transporter. Uptake transporters in liver may contribute to drug exposure, DDI, and toxicity of a therapeutic agent. Hepatic uptake transporters can also be targeted to selectively deliver therapeutic agents to the liver.

Hepatic uptake systems are divided into two classes, Na⁺-dependent and Na⁺-independent influx transporters (Fig. 6.6). The Na⁺-dependent bile acid uptake is mediated by the NTCP, while the OATP transporters, OATs, OCTs, and OCTNs transport a variety of organic anions through Na⁺-independent processes. Among the SLC superfamily, SLCO family, SLC22 family, and SLC10 gene family represent the predominant transport proteins that act as active carriers of organic anions across the sinusoidal membrane. Of the 11 functional human OATP transporters identified, only 3 isoforms (OATP1B1, OATP1B3, and OATP2B1) are currently believed to play an important role in hepatic uptake of exogenous therapeutics and endogenous compounds in hepatocytes [6]. OATP1B1, OATP2B1, and OATP1B3 are colocalized on the same membrane domain and have overlapping substrates, suggesting that inhibition of any one of the OATP would theoretically not cause a significant change in drug PK. While it is not easy to assess the relative contribution of each of these three transporters,

Figure 6.6 Schematic of apical and basolateral membrane transporters in human hepatocytes.

it is known that net inhibition of hepatic uptake can result in drug interactions and changes in systemic exposure and even unexpected toxicity. For example, in kidney transplant recipients receiving cyclosporine, a 3.8-fold increase in the area under the curve (AUC) of cerivastatin was observed [61] because of the inhibition of OATP1B1-mediated cerivastatin uptake into hepatocytes [62]. Recently, selective OATP inhibitors, such as estrone-3-sulfate for OATP1B1 and CCK-8 for OATP1B3, were used successfully to assess the relative roles of these isoforms in the hepatic uptake of pitavastatin, fexofenadine, and rosuvastatin [63].

Of the six distinct OAT members cloned from the human liver and kidney, OAT2 and OAT7 are predominately expressed on the sinusoidal membrane of hepatocytes. OAT7 shows 35–46% identity to other OAT family members and mediates an exchange of organic anions similar to other members from OAT family, but OAT7 has narrow substrate specificity, mainly encompassing sulfate conjugates in exchange for the four-carbon short-chain fatty acid butyrate [64,65]. The transport of cationic drugs is predominantly catalyzed by the OCTs. Of the three OCTs characterized, OCT1 is significantly expressed in the liver. The expression of OAT and OCT proteins is regulated by drugs and disease states. The activation of nuclear transcriptional factors by their respective ligands, such as aryl hydrocarbon receptor (AhR), constitutive androstane receptor (CAR), pregnane X receptor (PXR), and nuclear factor erythroid 2-related factor 2 (Nrf2), could alter the expression of a number of transporters in the hepatocyte [66]. For example, phenobarbital (acting through CAR) effectively decreases Oat2 expression in liver [66]. On the other hand, hepatic mRNAs for Oct1 and Oct3, but not for Oat2, were decreased in rats following lipopolysaccharide treatment [67].

6.4.3 SLC Transporters in Blood–Brain Barrier

The BBB consists of brain capillary endothelial cells with complex tight junctions that separate circulating blood and cerebrospinal fluid in the central nervous system. The high density cell layers of the BBB serve to regulate the transport of nutrients, waste products, and clinical agents in and out of the brain. The passive diffusion of small molecules across the BBB has traditionally been dependent on lipophilicity, in which modifications of this physiochemical property is a strategy to increase BBB permeability. We now know that similar to other organs such as the liver and intestine, distinct transport systems expressed in the apical and/or basolateral membrane can influence the selectivity of compounds across the BBB. Physiologically, the mechanism of BBB transport is divided into three separate processes: (i) blood-to-brain uptake of drugs and nutrients (e.g., glucose, nucleotides, and amino acids) [68], (ii) efflux ABC transporters including P-glycoprotein (P-gp/ABCB2) and BCRP (ABCG2) that prevent entry of xenobiotics into the brain, and (iii) brain-to-blood transport systems for elimination of metabolites, neurotransmitters, and neurotoxins [69]. The interplay of transporters at the BBB makes it possible to selectively restrict the distribution of many drugs and therefore enhances our understanding of the molecular mechanism governing brain penetration [70].

While ABC efflux transporters with broad substrate specificity act as a functional barrier restricting drug entry into the brain, several SLC members in the BBB may play a key role on the uptake of neuroactive compounds (Fig. 6.7). Originally cloned from human liver, SLC21A3 (OATP-A), is highly expressed in the brain, followed by kidney, liver, lung, and testis [71]. Uptake assays with mRNA-injected *Xenopus laevis* oocytes indicate that OATP-A is involved in the transport of δ -opioid receptor agonists such as D-penicillamine (2,5)-enkephalin and deltorphin II, suggesting its involvement in the transport of centrally active opioids [72]. Other members of the SLCO family, such as SLC21A9 (OATP-B), SLCO3A1 (OATP-D), SLC21A10 (OATP-E), and SLCO4A1 (OATP-F), are also detected in human brain. However, the exact localization and functions of these transporters are yet to be determined [12]. Most OAT members of the SLC22 family are found in the brain. Among those, OAT3 is the most abundant

Figure 6.7 Schematic of apical and basolateral membrane transporters in human BBB endothelial cells.

OAT localized to the basolateral membrane of brain capillaries [73]. Although OAT3 is also expressed in the liver, kidney, lung, and muscles [74], it appears to play a vital role in the entry of substrates into choroid plexus and in the exclusion of anionic metabolites of neurotransmitters from the brain [28,75].

Three OCTs OCT1–3 are reported expressed in the brain at varying levels. While OCT1 mRNA expression is believed to be negligible, OCT2 mRNA found in neurons and choroid plexus is reported to be involved in neuron uptake and reabsorption of substrates such as dopamine, norepinephrine, serotonin, histamine, and choline from the cerebrospinal fluid [38]. In the cerebral cortex and cerebellar and hippocampal neurons in rodents, OCT3 mRNA expression is greater than that of OCT1 and 2 [76,77]. Although there is no direct evidence, the ability to interact with cationic neurotoxins and neurotransmitters suggests that OCT3 may play a significant role in handling neuron active compounds in the brain [78]. In addition to OCT and OAT, OCTN1 and 2 are detected in neurons in hippocampus, cerebellum, spinal cord, and superior cervical ganglion [77]. Systemic and brain concentrations of acetyl-L-carnitine are decreased in Octn-2 gene knockout mice, suggesting that luminal expressed Octn-2 could assist the brain uptake of carnitine [79].

6.4.4 SLC Transporter in Kidney

The kidney is a principal excretory organ for endogenous substances and clinical drugs and their metabolites through the processes of filtration, tubular secretion, and selective or passive reabsorption. The active secretion and reabsorption of organic anion occur mainly in the proximal tubule region of the kidney, particularly in the renal proximal tubular cells. SLC transporters in these cells play an important role in several processes: (i) uptake of chemicals into the cells; (ii) drug efflux into the glomerular filtrate; (iii) reabsorption of drug from the filtrate; and (iv) drug efflux back into the blood. The active renal secretion of drugs is accomplished through a vectorial transport process in the renal proximal tubules, which consists of uptake from systemic circulation via the basolateral membrane and subsequent efflux into urine across the luminal membrane [3,80,81]. Renal tubular epithelial cells express a variety of transporter proteins that handle diverse substrates to mediate proximal tubular secretion and, in some cases, reabsorption to maintain body homeostasis. Renal transporters have been recognized as important determinants in drug elimination for many clinically used drugs [3]. There are two primary groups of carrier-mediated transporters (SLC22 family) for organic anions and cations. OATs, OCTs, and OCTNs play key roles in active renal proximal tubular secretion (Fig. 6.8). Additional kidney transporters include several members of the SLC family, such as the OATPs, sodium-phosphate transporter (SLC17A1, NPT), PepTs, ENT and CNT, and MATE1 and MATE2-K.

Among the renal transporters detected, OAT1, OAT3, and OCT2 are located on the basolateral membrane of renal proximal tubule cells [37,82] and mediate the uptake of a variety of organic cations or organic anions from systemic circulation. The OATs and OCTs transport a broad range of substrates, including endogenous metabolites, anionic compounds such as nonsteroidal anti-inflammatory drugs, and the β -lactam antibiotics. Three OCT isoforms, OCT1–3, are identified as the primary transporters involved in renal secretion of several marketed drugs such as metformin, amantadine, and memantadine [3,83–85]. OATs and OCTs mediate the uptake of organic cationic and anionic compounds in concert with efflux carriers on the luminal membrane to

Figure 6.8 Schematic of apical and basolateral membrane transporters in human renal proximal tubular cells.

translocate xenobiotics into urine. Decrease in renal secretion and CL may produce an increase in systemic drug exposure, thereby resulting in clinically significant changes in the overall drug PK. Competitive inhibition of proximal tubular secretion is the most common type of renal DDI, for example, probenecid (an OAT substrate and inhibitor) prevents excessive accumulation of cidofovir or cephaloridine in proximal tubular cells, resulting in reduced nephrotoxicity [60,86]. Similar to renal OATs, DDI may also result from the modification of OCT1–3 functions. For example, cimetidine reduces the renal CL of metformin and thus increases exposure (increase in AUC) of metformin in patients via inhibition of OCT2 activity [87]. Substrates taken up from the systemic circulation may subsequently undergo efflux across the brush border membrane of the proximal tubule cells by various ABC efflux transporters such as P-gp and BCRP [88]. MATE1 and MATE2-K are located in the brush border membrane of proximal tubular cells in humans and preclinical species, and facilitate renal secretion of structurally diverse compounds [89]. MATE2-K works collaboratively with OAT3 for vectorial transport of substrates in proximal tubular cells [10]. OAT expression may be modulated by disease states, for example, increased Oat1 expression is found in rats with bilateral ureteral obstruction [90]. Chronic renal failure induced by nephrectomy can result in a decrease of OAT1 expression [91]. Modulation of transporter expression under disease conditions can potentially modify the renal excretion of substrate drugs.

6.5 IN VITRO MODELS TO ASSESS SLC TRANSPORTERS

Cell- and membrane-based systems are used *in vitro* to characterize transporter-mediated interactions. Whole-cell models use transformed/immortalized cell lines or primary cells, while membrane-based models include membrane fragments or vesicles.

6.5.1 Cell-Based Models

6.5.1.1 Immortalized Cell Lines. These cell lines are used to assess the absorption and permeability potential of compounds in drug discovery. The cells are referred to as *wild type* when used as a control for the cells overexpressing specific exogenous transporter genes. Caco-2 and MDCK cell lines are the most widely used system in ADME research for evaluating the substrate and inhibition potential of drug candidates. Although synonymous with efflux transporters, particularly MDR1 (P-gp), these cell lines are routinely used to assess the extent of transport across the epithelium because of the presence of well-developed and functional tight junctions. Caco-2 and MDCK cells can be cultured on Transwell® permeable supports to establish confluent monolayers with high transcellular resistance, allowing for measurement of uptake (apical to basolateral) and efflux (basolateral to apical) of test compounds through the monolayer. The advantage of the Caco-2 cells is that these are of human colonic origin and have many enterocytelike characteristics, while the MDCK cells are from the canine kidney. However, while the Caco-2 cells require three weeks to establish adequate tight junctions to form a resistant monolayer, the MDCK cells can do this within a week, making these more cost-effective, while essentially providing equivalent data [92]. Caco-2 and MDCK cells express multiple endogenous transporters such as ASBT; amino acid (e.g., LAT2), peptide (e.g., PEPT1), and monocarboxylate (MCT-1) transporters for uptake [93–95]; and MDR1, BCRP, and MRP1–3 for efflux [96]. Consequently, these cell lines (and others, e.g., LLC-PK1 and HK-2) are widely used for evaluation of oral bioavailability and predictions of BBB and tumor permeability. Although under appropriate culture conditions these wild-type cell lines produce polarized monolayers, with transporters correctly inserted in the cell plasma membrane, these are likely not present in the same quantities or ratios as those in the cells *in vivo*. Owing to the overlapping substrate specificities of many SLC transporters and the lack of transporter-specific inhibitors and substrates, an appropriate strategy is to use wild-type cell lines for the initial screening of test compounds, and if significant transport is observed, overexpressed/recombinant transporter systems are utilized to identify the specific transporters.

6.5.1.2 Stably Transfected Cell Lines. These are the most widely used system for drug-transporter-based studies. The cell lines most commonly used for drug transporter transfections are MDCK and HEK-293. For uptake transporters, singly transfected cell lines suffice, for example, OATP1B1, OATP1B3, OATP2B1, OAT1, OAT3, and OCT2 [97,98]; however, if evaluating efflux, in some cases, the coexpression of uptake transporter(s) along with the efflux transporter may be necessary to fully evaluate efflux transport. Since MDR1 transports a wide variety of lipophilic substrates that can diffuse through the cell membrane, an uptake transporter is generally not required. However, MRP2 transports organic anions and conjugates and an uptake transporter, for example, OATP1B1 may be required to facilitate the uptake of MRP2 substrate compounds into

the cell [99]. Similarly, to assess efflux of bile salts via BSEP, a vectorial coexpression system may be needed in which cells are transfected with bile salt uptake transporter, NTCP, and the efflux transporter, BSEP [97]. Studies have shown that multiple uptake transporters can be transfected simultaneously, for example, the coexpression of major hepatic uptake transporters OATP1B1 and OATP1B3 or the renal uptake transporters OAT1, OAT3, and OCT2 to evaluate substrate uptake involving several transporters [100].

6.5.1.3 Transiently Transfected Cell Systems. The advantage of the transiently transfected systems is that only one cell line is propagated in culture and the transporter of interest is transfected when needed, reducing the burden of maintaining multiple stable cell lines. Transient transfection systems are comparatively cost and resource sparing, especially when supporting large drug discovery programs. The vaccinia virus system is a widely used model [101] that yields high expression levels, as the virus shuts down the host cell protein synthesis by hijacking the host cell resources to generate recombinant viral proteins. Alternatively, *Xenopus* oocytes can be used as a recombinant system in which mRNA is injected into the cells to express the transporter of interest. In general, the overexpression of the transporter protein in this system is tedious and low throughput. This system has been used to express uptake transporters and has been applied to evaluate drug CL and address drug–transporter interactions [102].

6.5.1.4 Primary Cells. A majority of transporter studies in primary cells have been conducted with rat or human hepatocytes. Both suspension [103] and plated [104,105] primary hepatocytes are effective to evaluate drug uptake, biliary excretion, and drug–transporter interactions. In culture, when sandwiched between two layers of extracellular matrix, these cells polarize and establish functional bile canaliculi, in which transporters localize correctly to the apical and basolateral membranes [106]. Cryopreserved hepatocytes preserve both drug-metabolizing enzymes and the major uptake and biliary transporters [107,108], although levels of these change over time in culture. *In vitro*–*in vivo* correlations of uptake CL have been demonstrated using primary hepatocyte cultures utilizing the well-stirred model [109]. Cultured human and rat hepatocytes can be used to evaluate the hepatotoxic potential of drugs due to inhibition of bile acid excretion [104] and OATP-mediated transport [110], providing insight toward the prediction of drug disposition and DDI. On the other hand, limited success has been observed for primary human renal proximal tubular cells for transporter-mediated studies. While uptake can be evaluated effectively in fresh suspensions, these cells tend to lose membrane transporter activity when placed in primary culture on plastic culture plates, possibly because of internalization of the transporter proteins (authors' unpublished observations). However, when these cells are plated on permeable supports, they establish transepithelial resistance of 100–200 ohm², enabling their use to assess bidirectional transport across the monolayer [111]. Typically, the cells are cultured for 8–10 days as monolayers on permeable filter supports. To date, mRNA has been detected for OCT2, OCTN2, OAT1, OAT3, OAT4, MDR1, MRP2, and BCRP and protein for OAT1 and OAT3 [112]. Functional activity studies have been conducted demonstrating that PAH is transported (likely via uptake across the basolateral membrane by OAT1 and OAT3) and creatinine is secreted by OCT2-mediated uptake at the basolateral membrane

and efflux by MDR1 at the apical membrane. Similarly, there are a limited number of studies using primary brain endothelial cells and none to our knowledge that investigated the SLC transporters.

6.5.1.5 Hepatic Couplets. The hepatocyte couplet model allows for the evaluation of uptake and biliary elimination of test compounds. The advantage of the couplets is that these are polarized cells with a distinct basolateral membrane interacting with the media/buffer and an apical bile canaliculus, which is the sealed lumen between the two adjacent hepatocytes. Rat couplets have been used to evaluate bile transport and Bsep function by monitoring the uptake of taurocholate [113], canalicular transport of the organic cation daunorubicin [114], and electroneutral uptake and electrogenic secretion of the fluorescent bile salt 7 β -NBD-NCT [115]. Although the data obtained from these studies is valuable, isolating and working with hepatic couplets requires high technical skill and is low throughput, likely accounting for the limited ADME studies with this model.

6.5.2 Membranes and Vesicles

Both membranes and vesicles are made by overexpressing the transporter of interest by transfection of a cell line, or from organ tissues, for example, liver canalicular membranes. In the case of cell lines, once the transporter is expressed, the cell membranes are isolated and the transporter can be purified from the cell membranes [116,117]. The cell membranes can be used as is or made into vesicles to assess transporter-mediated uptake into the vesicular space. At present, only the ABC transporters have been successfully assessed in cell membranes or vesicles. It is more challenging to assess SLC activity in these systems, as the transporters are either cotransporters, antiporters, or work down a pH or concentration gradient. At present, these conditions have not been worked out in isolated membrane vesicles.

6.5.3 Small Interference RNA (siRNA/RNAi)

The mRNA of interest is specifically knocked out by the introduction of antisense RNA into the cells, resulting in degradation of the corresponding complementary mRNAs in a gene-dependent manner and loss of expression of the target protein [118]. In cell lines, RNAi has been used successfully to silence activities of specific transporters, to identify the transporters responsible for L-DOPA renal transport (rBAT and LAT2) [119], and to identify ABCA1 as the transporter mediating the secretion of the A β peptide [120]. Partial knockdown of Mrp2 (50% expression) in rat primary hepatocytes resulted in a 45% decrease in the biliary excretion index of carboxy-dichlorofluorescein without effecting Mrp3 expression [121]. In the absence of specific substrates and inhibitors for transporters, siRNA may be an appropriate system to assess the contribution of specific transporters to test compound disposition in primary cells and wild-type cell lines.

6.6 IN VIVO MODELS OF TRANSPORT

Transporter studies can also be conducted *in situ*, using isolated perfused organs or *in vivo* in wild-type, genetic knockout, genetic knockin, transgenic, or humanized/chimeric animals. Combining *in vivo* and *in vitro* data, the model provides additional insights toward potential transporter-related issues in humans.

6.6.1 Isolated Perfused Organ Systems

Compared to the *in vitro* assays, the isolated perfused intestine, liver, brain, and kidney provide a relatively more physiological determination of transporter functions in absorption, biliary elimination, brain penetration, and renal excretion, while also allowing for evaluation of the contribution of drug-metabolizing enzymes. For *in situ* studies, the organ (typically rodent) is directly infused with a physiological buffer, artificial blood, plasma, or saline via a major blood vessel entering the organ (e.g., hepatic artery for the liver) and the test compound is added to perfusate and infused for predetermined times. Concentrations of test compound and metabolites are determined in the organ and at the point of exit from the organ. The advantage of the isolated perfused organ system is that the concentration of a drug in the organ of interest can be controlled [122]. An example of such a study is using the rat-isolated liver perfusion model to determine the AUC of digoxin in the presence and absence of the Oatp2 inhibitor rifampicin and the Mdr1 inhibitor quinidine. Concentrations of digoxin in the perfusate were increased by rifampicin and decreased by quinidine, indicating that rifampicin limits enzyme exposure to digoxin by inhibiting Oatp2-mediated uptake, whereas quinidine increases enzyme exposure to digoxin by inhibiting the Mdr1-mediated efflux [123].

6.6.2 Knockout and Transgenic Models

Since transporters have broad substrate specificity, knocking out one or more related transporters at a time can theoretically result in a more clear understanding of their *in vivo* function. Care has to be taken when extrapolating these predictions to humans, as there are major differences in the rodent and human transporters in terms of substrate recognition as well as the lack of orthologs, for example, in the kidney, rodents express both Oct1 and Oct2, while humans express only OCT2.

6.6.2.1 Oatp Transporters. The hepatic transporter Oatp was first studied in a knockout mouse model of Oatp1b2 using the Oatp1b substrates pravastatin and rifampin. The liver-to-plasma ratios were lower in the knockouts as compared to wild type, indicating that Oatp1b2 is involved in the hepatic uptake and CL of these drugs [124]. The *Slco1b2*^{-/-} mice also exhibited lower liver-to-plasma ratios of the HMG-CoA reductase inhibitor lovastatin, but not of cerivastatin or simvastatin acid, suggesting that Oatp1b2 contribution in hepatic statin uptake is variable [125]. The *Slco1b2*^{-/-} mice were protected from hepatotoxicity induced by phalloidin and microcystin-LR, indicating a role for Oatp1b2 in transporting these toxins into the liver [126]. Transgenic mice expressing human OATP1B1 were created by feeding the mice a semisynthetic diet to downregulate endogenous *Slco* genes. Methotrexate PK revealed a 1.5-fold lower AUC in OATP1B1-expressing mice as compared to the wild types [127]. *Slco1a/1b*^{-/-} mice demonstrate significantly reduced hepatic uptake and elevated exposure to methotrexate and fexofenadine after IV or PO administration [128].

6.6.2.2 OATs. Oat1^{-/-} and Oat3^{-/-} mice have demonstrated the *in vivo* relevance of these transporters in renal elimination of overlapping substrates. In kidney slices from Oat3^{-/-} mice, taurocholate, estrone sulfate, and PAH concentrations were reduced

relative to those from wild-type, while there was no difference observed in the liver, which does not express Oat3 [28]. Penicillin G PK was reduced by one-half in Oat1^{-/-} and Oat3^{-/-} male mice and by two-thirds in female Oat3^{-/-} mice [129]. Gender-related differences were also observed in methotrexate CL [130].

6.6.2.3 OCTs. Knockout mouse models for all three OCTs have been developed. In the Oct1^{-/-} mice, TEA accumulation was reduced significantly as compared with wild-type mice, indicating that Oct1 is the main sinusoidal uptake system for TEA in the liver [131]. Small intestinal excretion of TEA was reduced by about 50%, indicating that Oct1 also mediates the basolateral uptake of TEA into enterocytes [132]. Knocking out Oct1 from the mouse liver resulted in a shift in the elimination of Oct1 substrate drugs from hepatic to renal elimination, and consequently, renal excretion of drugs was increased [132]. Since the Octs have overlapping substrates, knocking out all three Octs could result in more definitive data. To assess this, Oct2 single-knockout and Oct1/2 double-knockout mice were generated [131]. While removal of Oct2 did not have a significant effect on elimination of TEA, in the double-knockout mice, renal secretion of TEA was completely eliminated and higher plasma levels were observed. Oct3-deficient mice showed significant reduction in MPP⁺ accumulation in the heart as compared with wild-type mice [133]. This demonstrates that when extrapolating data with genetically manipulated preclinical species, it is advisable to consider the effects on all organs and not just on the one of interest to that particular study.

6.6.2.4 MATE Transporters. Knockout models show that as compared to the wild-type animals, Mate1^{-/-} mice exhibit a twofold increase in systemic exposure to metformin as a result of the reduced renal CL [134]. Mate1^{-/-} mice demonstrate increased cisplatin-induced nephrotoxicity and increased plasma and renal concentrations relative to wild-type mice [135]. Reduced renal CL of cephalixin was also observed in Mate1^{-/-} mice relative to that in the wild-type mice [136]. These studies showed that, in humans, the interplay between OCT2 and MATE1 may likely affect the net renal secretion of shared drug substrates.

6.6.2.5 Limitations of knockout and transgenic murine models. Although some of the murine transporter orthologs being studied are eliminated in transgenic models, the presence of other murine-specific transporters with overlapping substrate affinities are still present, and therefore, data obtained is the result of a combination of human and murine events. Another problem is that deletion of one transporter can cause alteration in expression of other transporters and/or enzymes. For example, Mdr1a/1b^{-/-} and Mdr1a^{-/-} knockout mice had significantly increased levels of CYP3A, 2B, and 1A proteins and activities [137]. Moreover, many of the SLC transporters, for example, OATPs do not have animal and human orthologs. Moreover, these models do not recapitulate the role of regulatory proteins such as PXR, liver X receptor α (LXR α), and farnesoid X receptor (FXR), which are involved in regulating the key nuclear receptors governing expression of these transporters. While these models are useful in studying a particular transport protein, the results should be extrapolated with caution since the SLC transporter being assessed may not have a human ortholog or other elimination pathways may be up- or downregulated.

6.6.3 Chimeric/Humanized Murine Models

Potential future models that could reduce deficiencies in the transgenic models because of the lack of animal and human orthologs are “humanized” mouse liver animal models. Typically, human hepatocytes are transplanted into immunodeficient mice with compromised livers (e.g., SCID mice) and between 70% and 90% replacement of murine hepatocytes with human hepatocytes is reported [138,139]. Hepatic mRNA expression of human drug-metabolizing enzymes and transporters in these chimeric mice revealed that 21 of the 23 transporters found in the wild-type mice were expressed. These mice have mainly been utilized for PK studies and have not gained widespread use because of the problems associated with using immunodeficient animals, high costs, and highly variable data, likely because of differences in hepatocyte repopulation between the mice. More recently, a humanized mouse model has been developed in immunocompetent mice with normal liver function, using facile and ectopic implantation of a tissue-engineered human liver [140]. The juxtacrine and paracrine signals in the polymeric scaffolds appear to stabilize the function of cryopreserved primary human hepatocytes. These mice exhibit humanized liver functions that persist for weeks, enabling the evaluation of drug metabolism, DDI, and drug-induced hepatotoxicity. It is likely that these models will continue to improve and that “humanized” mice will prove to be an effective *in vivo* model for transporter-based evaluations.

6.7 CLINICAL EXTRAPOLATIONS

Relatively limited work has been published thus far on successful quantitative correlations. One method published by Hirano *et al.* proposes correlation methodologies and predicts the degree of inhibition for OATP-transporter-mediated drug interactions [141]. If the compound inhibits a probe substrate with an IC_{50} value $<10 \times$ the unbound inhibitor concentration, then the compound has the potential to illicit a clinical drug–transporter interaction with the OATPs. These authors have furthered the drug interaction prediction by developing an algorithm based on *in vitro* and *in vivo* data, known as the *Degree of Interaction* (R) and estimated by the following equation:

$$R = 1 + \frac{f_u \times I_{in, max}}{K_i}$$

$I_{in, max}$ is the unbound inhibitor concentration (C_{max}) at the entry point of the organ (e.g., in the hepatic portal vein for the liver or the renal artery for the kidney), f_u is the blood unbound fraction, and K_i is the inhibition constant. However, an IC_{50} value is typically utilized instead of the K_i . The $I_{in, max}$ is determined as

$$I_{in, max} = I_{max} + \frac{F_a \times Dose \times k_a}{Q}$$

where I_{max} is the maximum circulating plasma concentration, F_a represents the absorbed fraction of inhibitor, k_a is the absorption rate constant in the intestine, and Q is the hepatic blood flow rate in humans (1500 mL/min) [142]. As the ratio of $(f_u \times I_{in, max})/IC_{50}$ increases, the likelihood of an interaction will increase as well. The potential for drug interaction is minimal if the calculated R -value is close to

one and drug interaction potential is likely with R values >2 . These extrapolations are confounded by the fact that many drugs that actively enter the liver are also metabolized, and thus far, there is no effective method to account for the interplay between transport and metabolism toward quantitative predictions of drug interactions.

In the case of the kidney, the quantitative extrapolations must also factor in the glomerular filtration rate (GFR) of the test article. When $CL > GFR$, it indicates active elimination via renal transporters, and when $CL < GFR$, it indicates active reabsorption is present. When $CL = GFR$, it may indicate no active transporter interaction or the potential for simultaneous active efflux and reabsorption, in which the two mechanisms negate each other but transporter-mediated drug interactions may still occur.

While for the CYP450 enzymes there are sufficient *in vitro* – *in vivo* correlations to classify *in vitro* IC_{50} and K_i data as low-, medium-, and high-drug interaction liability, this is not the case with the SLC transporters. For hepatic transporters, the K_m and K_i values that appear to be relevant to a clinical endpoint are quantitatively similar to the CYP enzymes, for example, K_i values in single digits for the OATP transporters [105]. However, in the case of the renal secretory transporters, in some cases, the K_m and K_i values that appear to be relevant to a clinical endpoint [143,144] can be relatively high compared to those reported for the hepatic transporters or CYP enzymes and are closer to what is reported for the UDP-glucuronosyltransferase (UGTs) [145]. For example, the CL for acyclovir in humans is higher than the GFR at 2.6 mL/min/kg and the affinity (K_m) for OAT1 is 242 μM [146]. Similarly, hydrochlorothiazide, which is actively transported predominantly via renal OATs, also has a $CL > GFR$ (4.9 mL/min/kg) and a high K_i value (150 μM) for the renal transporter OAT1 [147]. Until there are better methodologies developed to relate *in vitro* K_m and K_i values, the potential to predict *in vivo* transporter-mediated interactions will be weak. An effective strategy is to include benchmark marketed compounds, preferably similar chemotypes, as a comparator, to help guide predictions of potential interactions.

6.8 INTERPLAY BETWEEN SLC TRANSPORTERS AND DRUG-METABOLIZING ENZYMES

Transporters expressed in various tissues contribute to the distribution of physiological substances (e.g., bile acids and cholesterol) and nutrients and removal of metabolic waste [148]. The extent of drug movement across membranes is generally affected by physicochemical properties such as size, lipophilicity, charge, and degree of ionization. As transporters contribute to the ADME, they invariably influence the PK properties of drugs. The SLC/SLCO uptake transporters facilitate the distribution of hydrophilic drugs into tissues for greater access to drug-metabolizing enzymes. However, a majority of drugs are lipophilic and do not require an active transport process, as they can traverse the lipid bilayer of the cell membrane passively by diffusion.

Drug bioavailability and hepatic disposition can be greatly influenced by transporter–metabolism interplay. The interplay between drug-metabolizing enzymes and drug transporters was first identified in the 1990s from cyclosporine interaction studies with ketoconazole (CYP3A inhibitor) and rifampin (CYP3A4 inducer), in which changes in cyclosporine PK were not consistent with alterations of gut and hepatic metabolism by these two modulators [149–152]. The interplay became more

TABLE 6.3 Drugs Displaying Potential SLC Transporter and Drug-Metabolizing Enzyme Interplay

Object	Transporter(s)	Drug-Metabolizing Enzymes	References
Rosuvastatin	OATP1B1	CL _{hep} = 10%; metabolism by CYP2C9; metabolism by UGT1A1 and UGT1A3	155
Atorvastatin	P-gp, OATP1B1, BCRP	CL _{hep} ~ 100%; CYP3A4 extensive, metabolism by UGT1A3	156–158
Cerivastatin	P-gp, OATP1B1	CL _{hep} ~ 100%; CYP3A4 and CYP2C8	159
Fluvastatin	OATP1B1	CL _{hep} = 95%; metabolism by CYP2C9 (75%), but also by 3A4 and 2C8	160,161
Simvastatin	OATP1B1	CL _{hep} ~ 87%; CYP3A4 extensive first-pass metabolism, with only 5% available systemically	162
Bosentan	OATP1B1, OATP1B3	CL _{hep} ~ 97%; metabolized by CYP2C9 and CYP3A4	163
Bromocriptine	OATP1B1	CL _{hep} ~ 100%; CYP3A4, extensively metabolized	164
Repaglinide	OATP1B1	CL _{hep} ~ 98%; CYP2C8 and CYP3A approximately equal in contribution	165,166

lucid when overlap of substrate specificity for CYP3A4 and the ABC transporter MDR1 was identified. In addition to MDR1, enzyme–transporter interplay was also observed with SLC transporters, in which the transporter facilitated drug uptake into tissues (GI tract and liver) and exposed the drug to the metabolizing enzyme (Table 6.3). After metabolism, transporters, such as MDR1, BCRP, and MRP2, may contribute to the efflux of the metabolite to bile and urine [153]. Thus, transporters can be viewed as aiding the access of drugs to drug-metabolizing enzymes, thereby facilitating metabolism to protect the body from a buildup of endogenous and exogenous substances, whereas drug efflux decreases the load on detoxification enzymes [154].

6.8.1 OATP Transporters

The most widely evaluated anionic drugs are statins (e.g., fluvastatin, cerivastatin, simvastatin, and pravastatin) and diabetes drugs such as troglitazone and repaglinide. Many of the statins undergo significant phase I and phase II metabolism (fluvastatin, simvastatin, lovastatin), while pravastatin is excreted largely unchanged [167–169]. Clinical evidence based on genetic polymorphism studies for SLCO1B1 (encoding OATP1B1) of c.521 T>C (p.Val174Ala) reveal increases in the plasma concentrations

of simvastatin acid and pravastatin, but no significant effect on fluvastatin [160], consistent with hepatic uptake being rate limited. As shown in Table 6.3, there are several examples that highlight transporter–enzyme interplay in drug disposition: fluvastatin (OATP1B1 and CYP2C9, and to a minor extent CYP3A4 and CYP2C8), repaglinide (OATP1B1, MDR1, and CYP2C8 and CYP3A4), and bosentan (OATP1B1, OATP1B3, and CYP3A4 and CYP2C9) [163,165,170]. In addition to drugs with uptake and CYP metabolism, atorvastatin and rosuvastatin are also metabolized by the UGT enzymes [156–158]. The combination of transporter–drug metabolism interplay results in significant and complex drug interactions that are difficult to predict using *in vitro* systems.

6.8.2 OATs/OCTs

There are limited publications on drug transporter–enzyme interplay for OAT and OCT substrates. Many of the anti-infective drugs are predominately eliminated by renal OATs, for example, Tamiflu and olmesartan. These two prodrugs undergo metabolism that requires esterase cleavage for activity, and subsequently, their carboxylate metabolites are exclusively renally eliminated [171,172]. Ciprofloxacin and dicloxacillin undergo hepatic metabolism; however, renal CL is the predominant pathway. Methotrexate has some involvement with xanthine oxidase and aldehyde oxidase [174], and zidovudine is metabolized by UGT2B7 in the kidney [175], but there is no drug transporter–metabolizing enzyme interplay linkage reported clinically. For the OCTs, procainamide (an antiarrhythmic agent) undergoes CYP2D6 metabolism, and 65% of the dose is excreted unchanged in the urine [176], and theophylline is predominately metabolized by CYP1A2 [177]. Similarly, no reported transporter–metabolism interplay has been reported for the OCTs.

6.9 TRANSPORTER-MEDIATED DRUG INTERACTIONS DUE TO INHIBITION

6.9.1 OATP Transporters

The interplay between SLC/SLCO transporters and drug-metabolizing enzymes can be quite complex when multiple drugs are coadministered. The cotherapeutics may enhance or reduce active transport across membranes, as well as modulate the activity of metabolic enzymes, resulting in larger than expected drug interactions [178]. The uptake of HMG-CoA reductase inhibitors pravastatin, pitavastatin, atorvastatin, and fluvastatin is saturable and has been shown to be rate limiting in rats and human hepatocytes [179]. As shown in Table 6.3, statins are metabolized by CYP3A4 (simvastatin and lovastatin) and have up to 20-fold increases in plasma concentrations in the presence of strong CYP3A4 inhibitors such as itraconazole and ritonavir. Potent inducers of CYP3A can greatly decrease plasma concentrations of simvastatin and simvastatin acid, and probably those of lovastatin and lovastatin acid, while pravastatin plasma concentrations are not significantly affected by CYP inhibition and only slightly affected by CYP inducers [160]. Human PK interaction studies have shown that CYP3A4 inhibitors clarithromycin and itraconazole modestly increase the area under the plasma AUC of repaglinide to ~40% [166]. However, the AUC of repaglinide increased 8.1-fold when coadministered with gemfibrozil [166]. The large drug

interaction with gemfibrozil and its glucuronide metabolite is attributed to inhibition of OATP1B1 and CYP2C8 [166]. Further, OATP1B1-mediated hepatic uptake of repaglinide is important for its elimination by CYP-mediated reactions as evidenced by elevation of repaglinide plasma levels in subjects with the OATP1B1 (521CC) genotype.

In comparison to other statins, pravastatin has greater hydrophilicity that limits its penetration into the intracellular space of nonhepatic tissues, which is consistent with its poor penetration through the BBB [180]. Pravastatin CL is equivalent between renal and nonrenal routes (i.e., biliary excretion and biotransformation), and therefore, dose adjustments are generally not required during hepatic or renal impairment. Furthermore, as metabolism by CYPs is minimal, this reduces the extent of drug interactions for pravastatin when compared to other statins that undergo extensive metabolism. Despite pravastatin having minimal CYP metabolism, drug interactions can be pronounced, for example, a 10-fold change in pravastatin AUC is observed when it is coadministered with cyclosporine (Table 6.3).

6.9.2 OATs

It is well documented that renal tubular secretion is inhibited by the coadministration of probenecid, which increases the circulating levels of penicillin and cephalosporin antibiotics [181,182]. Probenecid inhibits active renal transport processes via inhibition of OAT1 and OAT3 [183]. As shown in Table 6.4, probenecid alters the exposure of several antibiotics, pravastatin, fexofenadine, and some antiviral drugs, with a change in AUC from 11% to 260%.

6.9.3 OCTs

The number of significant drug interactions associated with OCT is limited. Apricitabine is a deoxycytidine analog nucleoside reverse transcriptase inhibitor for the treatment of human immunodeficiency virus-1 infection. Increased apricitabine drug exposure (AUC) of 66% and 42% was observed with concomitant administration of cotrimoxazole (trimethoprim/sulfamethoxazole) and tipranavir/ritonavir combination, respectively [201,202]. The extent of drug interaction observed for cimetidine and metformin was modest as the AUC of metformin increased by 54% (Table 6.3). Genetic polymorphism of OCT2 was evaluated in the Chinese population, and the 808G>T polymorphism was attributed to a reduced metformin renal tubular CL. Furthermore, this mutation correlated with the extent of cimetidine-mediated inhibition of metformin renal tubular secretion [203].

6.9.4 NTCP Transporter

To date, there are no published clinically relevant drug–transporter interactions with human NTCP. However, *in vitro* studies utilizing HeLa-NTCP cell lines and human hepatocytes have demonstrated that rosuvastatin uptake is mediated by this transporter, accounting for ~35% of its uptake into the liver [204]. Moreover, cyclosporine and gemfibrozil can inhibit the uptake of rosuvastatin with IC₅₀ values of 0.4 and 23 μM, respectively. Polymorphisms related to NTCP have shown that the NTCP*2 variant,

TABLE 6.4 Summary of OAT-Mediated Clinical Drug Interactions

Precipitant	Object	Object Therapeutic Class	Percentage Change in AUC	References
Probenecid	Cephadrine	Antibiotics	263.2	182
	Furosemide	Diuretics	167.9	184
	Cephadrine	Antibiotics	141.6	185
	Cephadrine	Antibiotics	138.8	186

Source: The data for this table was obtained from the University of Washington Metabolism and Transporter Drug Interaction Database.

which is known to have a near-complete loss of function for bile acids, exhibits elevated activity toward rosuvastatin uptake *in vitro*. Therefore, *in vitro* data suggest that NTCP may contribute toward the disposition of rosuvastatin, and consequently, inhibitors of this transporter may have the potential to cause a clinical drug interaction; however, the extent of the interaction in humans is not known.

Circulating levels of bile acid are dependent on the interplay between several transporters such as NTCP, BSEP, and MRP2/3/4 [205,206]. Animal models have shown that reduced expression of Bsep and inhibition of this transporter may explain impaired bile excretion leading to cholestasis [207]. Caution must be applied when extrapolating animal data to humans, as bosentan is a more potent inhibitor of rat Ntcp than human NTCP [208]. While NTCP may contribute toward the regulation of bile acids, there is no clinical evidence directly linking this transporter to cholestasis.

6.10 NUCLEAR RECEPTOR-MEDIATED SLC TRANSPORTER REGULATION

Similar to drug-metabolizing enzymes, hepatic transcriptional factors mediate the regulation of drug transporters. The major transcriptional factors involved in transporter-mediated regulation are AhR; CAR; PXR; FXR; PPAR α (peroxisome proliferator-activated receptor α); Nrf2; hepatocyte nuclear factors HNF1 α , HNF3 β , and HNF4 α ; LXR α ; and retinoid X receptor/retinoic acid receptor dimer (RXR α /RAR α).

6.10.1 OATP Transporters

The regulation of these uptake transporters has been reported with AhR, PXR, CAR, and PPAR, on the basis of rodent induction studies [209]. Hepatic mRNA expression was evaluated after treatment with AhR ligands (2,3,7,8-tetrachlorodibenzo-*p*-dioxin, polychlorinated biphenyl 126, and α -naphthoflavone) and Oatp2b1 was increased, and PXR activators (pregnenolone-16 α -carbonitrile and spironolactone) increased Oatp1a4, while CAR activators (phenobarbital, 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene and diallyl sulfide) decreased Oatp1a1 mRNA expression. PXR activators and PPAR α ligands (clofibrate, ciprofibrate, and diethylhexyl phthalate) decrease Oatp1a1, 1b2, 2a1, and 2b1 mRNA expression in liver, and Nrf2 activators (oltipraz, ethoxyquin, and butylated hydroxyanisole) downregulate Oatp1a1 and upregulate Oatp2b1 mRNA expression. In rodents, it appears that only a few transcriptional factors increase Oatp expression, while multiple factors decrease Oatp expression [209].

In humans, FXR, HNF1 α , HNF3 β , and HNF4 α transcriptionally regulate OATP1B1, OATP1B3, and OATP2B1 [210–214] by binding to the promoter region [212]. Site-directed mutagenesis revealed consensus binding sites in the 5'-flanking region from –38 to –24 bp for FXR, HNF1 α , and HNF3 β that are to be important for transcriptional activity of OATP1B3, as mutations in this region resulted in significantly decreased luciferase activity. Additionally, a vector containing the double mutant of HNF1 α and HNF3 β at the binding sites (–38 to –24 bp region) had significantly decreased luciferase activity as compared to the single transcriptional factor mutation. Using a different model, Kamiyama *et al.*, established an adenovirus vector expressing human HNF4 α -(hHNF4 α)-siRNA that selectively suppressed HNF4 α expression in human hepatocytes [212]. Data from this model suggests that OATP1B1 is directly regulated by hHNF4 α , unlike the CYP450 enzymes, which are indirectly regulated by HNF4 α via the upregulation of PXR and CAR expression in hepatocytes. Studies with the bile acid chenodeoxycholate (CDCA), the secondary bile acids deoxycholic acid (DCA) and lithocholic acid (LCA), endogenous ligands, and effective activators of FXR reveal a significant increase in OATP1B1 expression when FXR is activated [214].

6.10.2 OATs

Saji *et al.*, showed that deletion of Hnf1 α in mice (Hnf1 α null mice) resulted in a significant reduction of renal Oat1 mRNA levels. This was followed with the observation that promoter activity of Oat1 was stimulated by cotransfection of HNF1 α alone or the combination of HNF1 α and HNF1 β ; however, HNF1 β alone showed no effect [213].

For human OAT1, using the luciferase reporter gene assay, a series of 5'-truncated-promoter constructs of human OAT1 with or without the mutation in the HNF1 motif showed that HNF1 α alone, or HNF1 α and HNF1 β , bound to the promoter region within 111 bp upstream of the transcriptional start site significantly increased luciferase activity, confirming binding to the HNF1 motif [213]. HNF1 α /HNF1 α or HNF1 α /HNF1 β dimers were found to bind to the HNF1 motif in the OAT1 promoter [213]. Similarly, HNF4 α was shown to activate the OAT1 promoter in the regions spanning -1191 to -700 bp and -140 to -79 bp [215]. Kikuchi *et al.* showed that human OAT3 expression was transactivated by HNF1 α and HNF1 β . Similar to OAT1, there is a synergistic action of the HNF1 α /HNF1 α or HNF1 α /HNF1 β dimers toward transactivation and HNF1 β alone, and this does not activate expression of OAT3. Moreover, it was found that OAT3 promoter activity was repressed by DNA methylation [216].

6.10.3 OCTs

OCT1 is transcriptionally activated by HNF1 α , and two adjacent putative DNA-response elements interact with HNF1 α binding in the promoter region [212,217]. A luciferase reporter construct containing the OCT1 promoter was successfully activated by HNF4 α in transiently transfected Huh7 cells. Saborowski *et al.* showed that site-directed mutagenesis of either DR-2 element alone or in combination severely decreased the HNF4 α -mediated activation of the OCT1 promoter, indicating that both elements are functionally important [217]. In addition to HNF1/4 α , upstream stimulating factor (USF) 1 and 2 bind to the E-box regulatory element (CACGTG) of the proximal promoter, as deletion analysis suggested that the region spanning -141 to -69 bp was essential for the basal core transcriptional activity of OCT1 [218]. It appears there is coordination as the transactivation effect of USFs on the OCT1 promoter is further stimulated by HNF4 α binding.

In the case of OCT2, USF-1 binds to the E-box in the proximal promoter region, as a mutation of the E-box resulted in decreased OCT2 promoter activity, while the overexpression of USF-1 transcriptional factor enhanced OCT2 activity in a dose-dependent manner [219]. In addition, *in vitro* studies showed that methylation of the OCT2 proximal promoter resulted in significant reduction of transcriptional activity of USF-1 [220].

6.10.4 NTCP Transporter

The hepatocyte nuclear factors HNF1 α and 4 α and RXR α /RAR α bind and transactivate the rat but not the human or mouse NTCP/Ntcp promoters [221]. A 4-bp insertion in the HNF1 α recognition site located within the transcription start site of human and mouse NTCP/Ntcp gene resulted in a disrupted HNF1 α binding site and the transactivation of a consensus motif for the CCAAT/enhancer binding protein- β (CEBP- β) [221]. HNF3 β was found to be the only transcriptional factor with conserved binding sites in the 5'-regulatory region of the human, mouse, and rat NTCP/Ntcp genes. HNF3 β was found to repress NTCP activity by forming a specific DNA-protein complex, as assessed by electrophoretic mobility shift assays [221]. For RXR α /RAR α , Jung *et al.* suggested that a putative binding site for HNF4 α is localized with the RXR α /RAR α sequence based on coexpressed studies, in which rat Ntcp promoter activity increased two-fold [221].

On the basis of mutagenesis studies, a functional glucocorticoid receptor (GR) response element was identified in the promoter region of NTCP [222]. Dexamethasone increased reporter-linked NTCP promoter activity. Eloranta *et al.* showed that a DNA element arranged as a direct repeat of hexamers separated by nine nucleotides (DR-9) at nucleoside $-32/-12$ of the NTCP promoter mediates the glucocorticoid response and that GR directly interacts with this motif. The authors indicate that upstream and downstream elements are also required for full NTCP promoter transactivation activity by GR/dexamethasone. Adding more complexity, the induction of NTCP gene by GR in the presence of glucocorticoids can be enhanced by coexpression of the transcriptional coactivator, PPAR α (PGC-1 α) [222].

Bile acids may regulate NTCP/Ntcp indirectly by modulating the capacity of nuclear factors to activate gene expression [221]. When bile acid levels are elevated, the uptake of bile acids into hepatocytes from sinusoidal blood is reduced because of the reduced expression of NTCP/Ntcp in both rodents and humans [206]. In rats, bile acid-mediated suppression involves inhibition of the activity of the RXR α /RAR α heterodimer binding to the Ntcp promoter [221]. CDCA can cause reverse transcriptional activation of NTCP gene by GR/dexamethasone, and it has been proposed that GR is a target for negative feedback regulation of NTCP expression by bile acids in humans [222].

6.11 GENETIC POLYMORPHISMS OF SLC TRANSPORTERS AND CLINICAL IMPLICATIONS

Extensive human gene variation was reported after the near-complete sequencing of the human genome, with ~ 12 million single nucleotide polymorphisms (SNPs) identified [223]. These polymorphisms can occur in the regions coding for proteins (nonsynonymous polymorphisms) to give rise to amino acid changes or in noncoding regions of the genome (synonymous polymorphisms) to regulate the expression and function of proteins. Genetic polymorphisms could affect protein expression or functional activity via alteration of substrate affinity. Information from gene polymorphisms has advanced our understanding of the contribution of population PK variations to tolerability and safety profiles of therapeutics. Genetic variants may be associated with susceptibility to disease or important differences in PK/PD drug parameters. The PK and distribution of substrate drugs could be altered by the changes of transport capability caused by genetic variants. The variants might also affect the apparent activity of the transporter by lowering the affinity for substrates (K_m), and in some cases, they cause loss of function of the transporter.

Since membrane transporters handle many drugs that are prescribed clinically and regulate the ADME, these proteins play a critical role in pharmacological and toxicological processes. Genotypic and phenotypic polymorphisms in the SLC family contribute to interindividual, interethnic, and gender-based variability in PK and drug distribution. Transporter polymorphisms are associated with changes in efficacy, drug interactions, and safety concerns, including idiosyncratic hepatic toxicity. On the basis of the US Food and Drug Administration (FDA) *Guidance for Industry on Pharmacogenomics Data Submissions*, pharmacogenomics data is required for all known or probable valid biomarkers. The FDA also encourages submission of data for those genes (including

ADME genes) for which there is limited knowledge about the associated clinical variants. This pharmacogenetic information is needed to support scientific arguments and it could be included in the drug label.

6.11.1 OATP Transporters

Several genetic variants, including 388A>G (130Asn>Asp, rs2306283) and 521T>C (174Val>Ala, rs4149056), of the *SLCO1B1* gene that codes for OATP1B1 protein have been identified. The polymorphisms of OATP1B1 and 1B3 have been characterized to occur at different frequencies in various racial and ethnic populations. For example, the frequency of OATP1B1 c388G allele (*1b) in Caucasians, Asians, and African-Americans is about 40%, 60%, and 75%, respectively, and the 521T>C in codon 174 is ~15%, 15%, and 2%, respectively [6]. The polymorphisms have different activities that can affect PK and result in deleterious side effects. For example, individuals with the OATP1B1*5 or OATP1B1*15 haplotypes have increased exposure to the substrates including pravastatin, simvastatin acid, atorvastatin, and rosuvastatin, and this may result in myopathy or increased risk of hepatotoxicity. These variants also have a significant impact on the PK/PD profiles of substrate drugs. When OATP1B1 polymorphisms were mapped in individuals taking simvastatin, a significantly increased risk for myopathy correlated with increased tissue exposure and Val174Ala polymorphism [224]. Cerivastatin was withdrawn from the market because of a serious adverse effect rhabdomyolysis, which has been related to the variants in *SLCO1B1* with an odds ratio of 1.89, but not the variants of CYP2C8 or UGTs that metabolize cerivastatin [225]. When transfected with the variant *SLCO1B1**15 gene (rs2306283+rs4149056), HEK cells uptake activity with cerivastatin is reduced ~40% compared with the cells expressing the *SLCO1B1* wild-type gene [225]. The reduced transport capability is associated with decreased liver uptake of cerivastatin, leading to increased systemic exposure and risk of rhabdomyolysis. Pravastatin is an OATP1B1 substrate that is minimally metabolized and mainly excreted into bile unchanged. There is an ~10-fold variation in the AUC between individuals mainly because of the genetic polymorphisms in OATP1B1 that reduce elimination, thereby causing a significant increase in plasma concentrations of pravastatin. [226].

Genetic polymorphisms in regulatory regions of *SLCO* genes regulate the expression level of OATPs [227]. For example, OATP1A2 is expressed in brain capillary endothelial cells and contains one genetic variant located in a putative HNF1 α binding site [228].

6.11.2 OCTs

Western blotting and mRNA quantification in human liver samples revealed that expression of OCT1 and OCT3 was highly variable between individuals. A reduced expression associated with nonsynonymous coding variants of OCT1 (rs12208357) or OCT3 (rs2292344) was reported [229]. OCT transports metformin into hepatocytes, and the functional loss of variants of OCT1 is linked to the reduced hepatic uptake of metformin and subsequently, its PD effect [230]. Individuals carrying reduced function OCT1 alleles, including SNPs in positions 420, 401, and 465, appear to have reduced metformin CL based on the observed higher AUC and C_{max} [230].

Doors are opening to a new paradigm in drug development and therapy through pharmacogenetic research with human drug transporter proteins, which could lead to a clearer understanding of the individual susceptibility to drug toxicity and efficacy.

6.12 REGULATORY GUIDANCE FOR SLC TRANSPORTERS

The European Medicines Agency (EMA) issued a draft guideline on the investigation of drug interactions that included a section on drug transporters, in April 2010 and the Food and Drug Administration (FDA) issued a draft guidance for drug interaction studies in February 2012 that provides a more detailed information on drug interaction studies, including decision trees for the SLC (and ABC) transporters.

6.12.1 FDA Drug Interaction Guidance

As per the FDA guidance, all investigational drugs should be evaluated *in vitro*, using transfected cell lines and empty transfected cells to subtract out the background by endogenous transporters. Inhibition studies should be conducted *in vitro* for the hepatic transporters OATP1B1 and OATP1B3 and the renal transporters OAT1, OAT3 and OCT2, as well as the ABC transporters MDR1 and BCRP. Substrate assays for the hepatic transporters OATP1B1 and OATP1B3 are required when hepatic clearance is more than or equal to 25% of the total clearance. *In vitro* substrate assays for the three renal transporters are required when their renal active secretion is more than or equal to 25% of total clearance. The EMA includes the above transporters as well as OCT1 and BSEP, the latter being important for safety testing. An interaction is considered significant if uptake into the transfected cells is ≥ 2 fold of that in the empty vector transfected cells and can be inhibited by $\geq 50\%$ by a known inhibitor. The FDA guidance suggests that when evaluating drug candidates, selection of the interacting drugs should be based on established, relevant and strong inhibitors of the transporter pathways under investigation. Additional transporters: MRPs, MATE and BSEP are mentioned and it is suggested that these be considered when appropriate.

For clinical studies, the FDA advises that the choice of substrate for a particular transport pathway be based on the therapeutic area and most likely to be co-administered drugs, whose PK is markedly altered by known specific inhibitors of the transporter pathway, so as to enable the largest impact of the interacting investigational drug. The FDA acknowledges that the observed clinical interactions may be a result of inhibition of multiple pathways, if the investigational drug is also an inhibitor for multiple pathways.

6.12.2 EMA Drug Interaction Guidance

The EMA suggests that *in vitro* studies be conducted to assess substrate and inhibition potential of new drug candidates with OATP1B1, OATP1B3, OCT2, OCT1, OAT1, OAT3 and the efflux transporters P-gp and BCRP and also BSEP for pharmacodynamic and safety monitoring. *In vitro* inhibition assays are suggested for all the transporters. To assess the clinical substrate potential of an investigational drug for a particular transporter, the EMA suggests the transporter be evaluated if it contributes to the absorption, distribution or elimination of a compound. For distribution, evaluating *in*

vitro data along with tissue specific expression of the transporter, data on distribution in preclinical species, clinical safety data in patients with altered transport due to genetic polymorphism and expected clinical consequences of altered distribution should be considered.

The EMA guideline recommends that if renal and biliary secretion account for $\geq 25\%$ of systemic clearance, the transporter(s) involved in the active secretion should be identified. Potential OATP uptake should be investigated *in vitro* for non-cationic drugs with $\geq 25\%$ hepatic elimination. The contribution of biliary secretion should be based on available mass balance and interaction data, pharmacogenetic information and hepatic impairment, if any. Renal secretion should be estimated by comparing total renal clearance to renal filtration clearance of the unbound drug, similar to the FDA guideline.

The recommended time line for *in vitro* evaluations is before Phase II clinical trials; unless all concomitant drug treatments are not expected to have interactions and *in vivo* interaction studies should be conducted prior to Phase III. The EMA also suggests that the possible effects of transporter-enzyme interplay, such as between Pgp and CYP3A, should be discussed, and if required, clinical studies considered.

The major differences between the two guidelines are the inclusion of OCT1 and BSEP as major transporters suggested by the EMA, while this is not a part of the FDA guidelines. In addition, while the FDA guidance allow for IC_{50} values to be calculated, the EMA recommends K_i values.

6.12.3 Induction

The FDA and EMA guidance also discuss induction of transporters. Since expression levels of these transporters are regulated in coordination with metabolizing enzymes by activation of the same nuclear receptors, induction of CYP1A2, CYP2B6 and CYP3A4 can be used as the initial evaluation of the induction potential of an investigational drug on transporters. The definitive studies continue to be clinical induction studies. For example, induction of CYP3A4 by the drug candidate will serve as a trigger for a clinical P-gp induction study, using digoxin as the probe substrate.

6.13 SUMMARY

While earlier studies with transporters were conducted primarily with the ABC family, particularly MDR1, the SLC transporters are now considered equally important in the disposition of xenobiotics within the body and continue to be extensively evaluated. There is a significant amount of work being conducted that this review has not discussed. For example, we were not able to cover all transporters involved in drug disposition, for example, amino acid transporters such as System L (LAT) are not included. We have mentioned but not discussed the differences in transporter expression, regulation, and activity across ethnic groups and between different age groups mainly because there have been very few studies on this so far and we have limited knowledge of the effect of these on ADME. Another gap in this review and also in current knowledge is information on the number of binding domains in individual SLC transporters, similar to what has been reported for ABC transporters such as MRP2. Megaraj *et al.* developed transporter cells lines with MRP2 and various SNPs and

found that SNPs located in the MRP2 nucleotide-binding domains variably decreased the transport of all substrates studied; an SNP in the membrane spanning domain 1 selectively decreased the apparent affinity for glutathione and glucuronide conjugated substrates, and an SNP in the carboxyl terminus altered only bile acid transport [231]. The presence of multiple binding sites further complicates transporter evaluations, and these need to be identified for the SLC transporters as well. Most importantly, we still do not have adequate models to extrapolate *in vitro* transporter data to *in vivo*, and the different models currently available can result in very different outcomes. For example, fluvastatin uptake by OATP1B1, 1B3, and 2B1 is inhibited 60–90% by gemfibrozil in the transfected cell lines but only by 27% in the more intact primary hepatocytes, indicating that there is more to fluvastatin transport than uptake by these three transporters [161]. It is clear that we still have a long way to go in understanding the SLC transporters and their significance in ADME, and this story will evolve as the data unfolds.

ABBREVIATIONS

Transporters

ABC	ATP-Binding Cassette
ASBT	Sodium-Dependent Bile Salt Transporter
BSEP	Bile Salt Export Pump
CNT	Concentrative Nucleoside Transporter
CT	Na ⁺ /Carnitine Cotransporter
ENT	Equilibrative Nucleoside Transporter
LAT	System L Transporter
MATE	Multidrug and Toxic Compound Extrusion Transporter
MDR1	Multidrug Resistance Protein 1
NTCP	Sodium Taurocholate-Cotransporting Polypeptide
OAT	Organic Anion Transporter
OATP	Organic Anion-Transporting Polypeptide
OCT	Organic Cation Transporter
OCTN	Organic Cation Transporter Novel
SLC	Solute Carrier
UGT	UDP-Glucuronosyltransferase
URAT	Urate Transporter

Nuclear Receptors

AhR	Aryl Hydrocarbon Receptor
CAR	Constitutive Androstane Receptor
FXR	Farnesoid X Receptor
GR	Glucocorticoid Receptor
HNF	Hepatocyte Nuclear Factor
Nrf2	Nuclear Erythroid 2-Related Factor 2
PPAR	Peroxisome Proliferator-Activated Receptor

PXR	Pregnane X Receptor
RXR	Retinoid X Receptor
SNP	Single Nucleotide Polymorphism

ADME Terms

AUC	Area Under the Plasma Concentration Time Curve
BBB	Blood-Brain Barrier
CL	Clearance
DDI	Drug–Drug Interaction
GFR	Glomerular Filtration Rate
PK	Pharmacokinetics

Chemicals

6-CFL	6-Carboxyfluorescein
MPP ⁺	1-Methyl-4-Phenylpyridinium
PAH	<i>para</i> -Aminohippuric Acid
TEA	Tetraethylammonium

7.1 INTRODUCTION

Drug metabolism represents an integral contributor to the many physiological processes that govern the pharmacokinetic/dispositional fate of most therapeutic agents [1]. For the most part, drugs are taken orally and in order to be absorbed through the stomach and intestine, they need to possess a high degree of lipid solubility [2,3]. The requirement for drug lipid solubility is a physicochemical consequence to the fact that lipid-soluble (nonionized) molecules are able to pass through biological membranes by simple diffusion, while water-soluble (ionized) molecules cannot [4,5]. In this light, drug metabolism can be broadly described as the biological transformation of lipophilic, nonpolar molecules (drugs) to more hydrophilic, polar molecules (metabolites), which are in turn readily eliminated from the body. Restated, drug metabolism controls the systemic exposure of many drugs and without a metabolic pathway associated with drug clearance, these molecules would remain in the body for an extended period and possibly accumulate to toxic levels on repeated administration. In response to the role drug metabolism has in drug safety, regulatory agencies place a premium on gleaning information around the metabolic pathways and products associated for all new drug applications (NDAs) (e.g., Guidance for Industry: Safety Testing of Drug Metabolites).

In order to appreciate the role of drug metabolism in drug safety, it is important to consider how molecules are actually eliminated from the body. For the most part, molecules are removed from the body through two primary routes of elimination: the urinary and gastrointestinal systems [6]. The primary function of the kidney is the excretion of body wastes, and for the purpose of this chapter, drug metabolites. Renal elimination of drug metabolites is primarily dependent on the fraction of molecules that are susceptible to reabsorption in the distal renal tubule. In this region of the kidney,

nonionic diffusion is responsible for the reabsorption [7]. Reabsorption occurs primarily by passive transfer and is mediated by a large hydrogen ion gradient between plasma and acidic urine. In this environment, metabolites, which are typically ionized, remain in the urine and are excreted, while drugs that are generally present as nonionized molecules, readily diffuse from the urine back into circulation [8].

Extraction via biliary and intestinal excretion of drug metabolites is important for the elimination of many therapeutic classes of drugs and corresponding metabolites [9]. Typically, biliary excretion is usually the primary route of elimination for compounds with a molecular weight of more than 400 Da and generally involves active secretion rather than passive diffusion [10]. Specific transport systems appear to exist for certain classes of molecules (e.g., organic bases, organic acids, and neutral substances) [11]. However, given that the molecules most likely to be excreted via biliary elimination are large, ionized molecules, once a molecule has been excreted into the bile (and subsequently delivered into the intestinal tract), it is not likely to be reabsorbed by passive diffusion.

If we disregard the role of small molecule transporters in drug metabolite elimination, it is clear that the biliary elimination of drug metabolites, similar to renal excretion, is primarily mediated by the physical properties of the molecule. Those substances that are ionized typically leave the body, while lipid-soluble molecules can be reabsorbed and reenter the blood circulation, which lengthens their half-life in the body and potential for toxicity [12,13].

The process of drug reabsorption is conceptually similar to the manner in which any molecule distributes between the two phases of water and a lipid-like solvent. With respect to the drug metabolites, the two phases are fatty tissue (cell membrane) and water (plasma). In organic chemistry, this concept is described in terms of a quantitative feature, the partition coefficient P , or as it is usually expressed, $\log P$ [14]. Factors that influence $\log P$ can be further distilled into descriptors such as size and polarity or hydrogen bonding capability of a molecule [15]. Therefore, it is important to understand the chemical features that can influence the partition ratio of a molecule as these concepts are the primary areas of chemical modifications associated with drug metabolism and safety [16].

Generally, polar solute molecules will dissolve in polar solvents and nonpolar solute molecules will dissolve in nonpolar solvents. Polarity in organic chemistry refers to a separation of charge and can describe a bond or an entire molecule [17,18]. The polarity of the molecule is the sum of all the bond polarities in the molecule [19]. Since the dipole moment is a vector (a quantity with both magnitude and direction), the molecular dipole moment is the vector sum of the individual dipole moments [20]. Restated, polar solute molecules have a positive and a negative end to the molecule. If the solvent molecule (water in the case of biological systems) is also polar then positive ends of solvent molecules will attract negative ends of solute molecules (Fig. 7.1).

As described above, drug metabolites are typically described as either being weak acids (a substance that gives up a proton) or weak bases (a substance that accepts a proton) and because of this, the disposition of most drug metabolites are governed by passive diffusion [21]. The extent to which a given drug metabolite exists in an ionized and nonionized species varies at different pH values. Therefore, the pH, or more specifically the hydrogen ion concentration, influences the ratio of ionized to nonionized species for a particular drug metabolite (Fig. 7.2). This concept is expanded

Figure 7.1 Hydrogen bonding of urea in water.

using the Brønsted–Lowry definition of acids and bases. The thermodynamic character that relates the charge in a molecule to the pH is the ionization constant, pK_a [22].

With respect to the elimination of drug metabolites, an understanding of the degree of ionization of a given molecule under physiological conditions is helpful to predict whether a metabolite will be long lived. At a particular pH, the relative concentration of the ionic and the molecular moieties of a given drug metabolite can be described by the Henderson–Hasselbach equation:

$$pH = pK_a + \log \frac{[\text{conjugate acid}]}{[\text{conjugate base}]}$$

Therefore, it follows, from the Henderson–Hasselbach equation, that when a substance is half ionized and half nonionized at a certain pH, its pK_a is equal to this pH. In other words, when the pH is equal to the pK_a value of the molecule, half of the molecules of a drug are in ionized and half are in nonionized form. It is important to consider that the relation between ionization and pH is not linear, but sigmoidal. Thus, small changes in pH will result in great changes in ionization, particularly if pH and pK_a values are close together.

With an appreciation of the physical chemical requirements that are required for the elimination of the drug metabolite, the next obvious question is what types of chemical modifications are biologically available to support drug metabolism enzyme reactions? The chemical routes by which drugs are susceptible to drug-metabolizing enzymes are large and varied. In fact, one particular feature that distinguishes drug-metabolizing enzymes from other “classical” enzymes is the wide variety of reactions that these enzymes can carry out. In 1959, Williams classified the drug metabolic reactions that are catalyzed by this group of enzymes into two general phases: phase I and II reactions [23]. Phase I reactions include oxidation [24], reduction [25], and hydrolysis [26], whereas phase II reactions are broadly defined as conjugation reactions and include glucuronidation [27], sulfation [28], acylation [29], methylation [30], and conjugation with glutathione (GSH) [31].

As with all enzyme-mediated reactions, drug-metabolizing enzymes are capable of accelerating a chemical reaction faster than reactions carried out on a laboratory bench top under the mild conditions of aqueous solution, room temperature, and neutral pH.

Figure 7.2 Examples of acids and acidity scale.

In terms of the concepts describing chemical thermodynamics, enzyme catalysis is essentially a lowering of the free energy function (G) associated with a given chemical reaction [32]. A change in free energy for a reaction, ΔG , determines if a reaction is spontaneous or not. Equilibrium conditions are governed by the standard free energy change ΔG° , and there are several means by which enzymes are able to decrease activation energy. The catalytic power and specificity of an enzyme is a reflection of the steric and electrostatic features associated with the enzyme's active site [33]. The most important of these involves the enzyme initially binding the substrate allows the molecule to exist in close proximity to the catalytic groups found within the active enzyme

Figure 7.3 Free energy or potential energy diagram of a simple E2 elimination reaction of an alkyl halide to yield an alkene.

complex [34,35]. When the substrate is bound to the enzyme, the enzyme changes conformation and forces the substrate into a strained or distorted structure that mimics the reaction transition state [36], thus reducing the energy of activation (Fig. 7.3). In this conformation, the substrate is forced into a reactive state, due to the loss of the substrate's translational and rotational entropy, toward the total activation energy [37].

Although small in relative numbers, drug-metabolizing enzymes are able to catalyze a large variety of reactions because of their structural and chemical diversity. Some drug metabolism enzymatic reactions mimic organic chemistry reactions and proceed

via nucleophilic attack [38]. In this instance, enzyme's active residues can act as nucleophiles such as the sulfhydryl group of cysteine or the phenolic group of tyrosine. Alternatively, groups such as aspartic acid, glutamic acid, and histidine (as its conjugate acid) can act as general acids [39], while groups such as histidine, lysine, and arginine can act as general bases [40] in catalytic mechanisms. In contrast, while some drug-metabolizing enzymes can carry out their catalytic activity themselves, most others (phase I oxidative enzymes) require presence of cofactors and coenzymes to carry out reactions.

Coenzymes are organic molecules (often vitamins or vitamin derivatives) that are required by certain enzymes to carry out catalysis (Fig. 7.4). They bind to the active site of the enzyme and participate in catalysis but are not considered substrates of the reaction. Generally, coenzymes function as intermediate carriers of electrons, specific atoms, or functional groups that are transferred in the overall reaction [41]. An example of this would be the role of nicotinamide adenine dinucleotide phosphate (NADPH) in the transfer of electrons in certain coupled oxidation reactions [42]. In contrast, the term *cofactor* often refers to *inorganic substances* such as "metals" that are required for enzyme catalysis. In many instances, these metals are bound tightly by the enzyme or are complexed within prosthetic groups to form a permanent part of the protein structure. For example, cytochrome P450 enzymes derive catalytic function through a heme-complexed metal species (Fig. 7.4), through the formation of a reactive oxoiron(IV)-porphyrin π -radical cation, and are able to facilitate a wide range of reactions most notably the insertion of an oxygen atom between a carbon hydrogen bond [43].

While the notion of drug metabolism was appreciated before the 1950s, little was known about the oxidative source involved in these enzymatic reactions. However, in 1950s, several laboratories demonstrated the direct incorporation of molecular oxygen into small molecules [44–46]. In addition, during the same time period, other groups determined that the microsomal deamination of amphetamine [47] and dealkylation of aminopyrine [48] also required the presence of both the reduced form of NADPH and molecular oxygen (O_2) [24].

As illustrated in Fig. 7.5, the biological conversion of molecular oxygen to water involves four sequential one-electron reductions. The sequential nature of the reduction is necessitated by the fact that in the ground state, oxygen contains two unpaired electrons. Each stage of oxygen reduction generates a reactive intermediate, which can exist in a number of different energy levels or spin states and can generate new species, generally by the addition of a proton. This has special significance with regard to phase I drug-metabolizing enzymes that use oxene and hydrogen peroxide as the major oxygen species involved in oxidative drug metabolism reactions [49,50].

With respect to phase II drug-metabolizing enzymes, the chemistry that supports metabolite formation requires the presence of a cosubstrate. In these reactions, a foreign compound is covalently linked with a small endogenous molecule, derived from carbohydrate or amino acid sources, to yield a characteristic product known as a *conjugate* [23]. There are five major conjugation reactions that primarily make up phase II drug metabolism: glucuronidation, sulfation, acylation, methylation, and GSH conjugation. The corresponding cosubstrates involved in the listed reactions are listed in Fig. 7.6. Interestingly, while phase II reactions are collectively described as conjugation reactions, they differ greatly in terms of the nature of the substrates involved, their distribution through the body, and reaction mechanisms [51,52].

Figure 7.4 Structures of common phase I coenzymes and cofactors.

The biochemical tools used to understand the various mechanism of drug metabolism can be categorized into three primary groups: (i) experiments that are aimed to elucidate the factors that can affect the metabolite transition state; (ii) studies that characterize reaction pathways associated with product formation; and (iii) determinations of enzyme's active topography and influence on rates of metabolite formation.

Figure 7.5 Reduced states of oxygen.

Kinetic deuterium isotope effect studies have been used extensively to understand the mechanism of drug metabolism reactions [53]. Primary kinetic isotope effects refer to processes in which the bond to deuterium (usually a C–D bond) is broken during the reaction and are expressed as the ratio of the specific rate constants, $k_{\text{H}}/k_{\text{D}}$, for the initial reaction of the protium- and deuterium-labeled compounds, respectively. The thermodynamic basis for the primary deuterium isotope effect lies in the large relative mass difference between H and D, which results in a difference (1.2–1.5 kcal mole) between the zero-point energy of a bond to deuterium versus hydrogen [54]. This difference results in a greater energy requirement for cleavage of a bond to deuterium and as a consequence, isotope effects on the rates of metabolic processes where rupture of a C–D bond is rate determining.

In addition to helping define the thermodynamics of an associated drug metabolism reaction transition state, selective use of isotopes (in particular, D and ^{18}O) has also been applied to dissect the nature of drug-metabolizing reactions [55]. For example, the mechanism by which most aromatic hydroxylations occur is via epoxidation of electron-rich π -bonds in the ring [56]. The resulting arene oxide is highly reactive for two main reasons: (i) three-membered rings are highly strained and open up readily and (ii) the ring on which the arene oxide forms is no longer aromatic (one double bond was used to make the epoxide). As a consequence, arene oxides can undergo two main types of reactions: rearrangement to yield a phenol or epoxide opening by reaction with a nucleophile. One of the first applications of selective deuterium labeling in drug metabolism was toward understanding the mechanism of reaction for the enzymatic conversion of naphthalene to 1-naphthol in rat microsomes [57]. The results of this experiment suggested that on enzyme-mediated oxidation of the aromatic ring to the corresponding *para*-phenolic metabolite, the deuterium was retained on the molecule (NIH shift), a result of rearrangement via a ring-opened intermediate [58].

In view of the widespread occurrence of oxidative transformations in drug metabolism, experiments with isotopically labeled oxygen ($^{18}\text{O}_2$ or H_2^{18}O) have been used extensively to characterize many drug metabolism reaction mechanisms [59,60]. A good example of the application of heavy oxygen to determine the mechanism of drug metabolism is through a series of *in vitro* experiments that were carried

Figure 7.6 Structures of common phase II cosubstrates.

out under atmospheres enriched in $^{18}\text{O}_2$ and showed, by GC-MS analysis, that the dihydrodiol metabolite, 1,2-dihydro-1,2-dihydroxynaphthalene, contained only one atom of ^{18}O and that this labeled oxygen occupied the 1-position. In this study, the authors further inferred that the second oxygen atom was derived from water [61]. Subsequent experiments conducted by Jerina and others [62] verified this hypothesis by incubating the molecule in H_2^{18}O fortified rat liver microsomal preparations.

Site-directed mutagenesis of proteins has developed into a powerful tool for studies of structure–function relationships for many drug-metabolizing enzyme systems. The strategy of these types of studies is to alter enzyme’s amino acid residues that affect reaction features such as substrate specificity [63], catalytic competence [64,65], cooperativity [66], and product specificity [67]. In the past few years, advances in X-ray crystallography, homology modeling, and substrate docking techniques have allowed for more precise functions for drug-metabolizing enzyme residues, making it possible to utilize site-directed mutagenesis designed to test these predictions [68]. The primary aim of site-directed mutagenesis to investigate the catalytic mechanisms behind drug metabolism reactions is to replace essential residues (ionizable or nucleophilic amino acids) with unreactive ones [69,70]. In this fashion, general acids, general bases, and catalytic nucleophiles arguably represent the most “essential” residues in an active site as they directly participate in the formation and rupture of covalent bonds. For example, it has been proposed that the catalytic mechanism for uridine diphosphate glucuronosyltransferase (UGT) enzyme glucuronidation employs a serine proteaslike catalytic mechanism in which an Asp-His pair in the active-site deprotonates the hydroxyl on the substrate, which allows for nucleophilic attack on the sugar donor [71,72]. In an experiment carried out by Patana *et al.* [73], when the His37 residue of UGT1A9 was replaced with an alanine, drug metabolism studies conducted with the mutant enzyme revealed that His37 was not critical in UGT1A9 N-glucuronidation reactions, but was in O-glucuronidation reactions. The authors were able to conclude that for UGT1A9 reactions, *O*-nucleophiles require the active-site histidine residue to deprotonate them so that they become effective nucleophiles, while *N*-nucleophiles develop a formal positive charge during the reaction and thus requires a negatively charged active-site residue to stabilize the reaction transition state.

As described earlier, unlike most “traditional” enzyme systems, the group of enzymes that are loosely termed as *drug-metabolizing enzymes* exhibit considerable structural and catalytic diversity. For the most part, drug-metabolizing enzymes are capable of carrying out specific reactions. The multiplicity of various drug-metabolizing families was recognized more than 30 years ago [74,75]. Because most drug-metabolizing enzyme systems are actually a collection of isozymes, they have been broadly classified into families and subfamilies on a genetic basis [76,77]. For most drug metabolism enzyme families, there is some degree of substrate structural class preference within families and subfamilies, although some overlap in substrate recognition is observed [78,79]. However, independent of which isozyme is actually responsible for a drug metabolism reaction, it should be remembered that enzymes that make up a particular family, share the same chemical mechanism of catalysis. To this end, the scope of this chapter avoids any detailed description of any drug-metabolizing isozymes and will rather focus on the different reactions catalyzed within each family of drug-metabolizing enzymes and the chemistry involved in phase I (Section 7.2) and phase II (Section 7.3) reactions.

7.2 PHASE I DRUG METABOLISM REACTIONS

7.2.1 Cytochrome P450

Mammalian cytochrome P450 monooxygenases are heme-containing, membrane-bound enzymes that catalyze the oxidation and reduction of a variety of xenobiotics

Figure 7.7 Examples of P450 metabolism reactions.

and endobiotics (Fig. 7.7) [80]. P450s require a redox partner protein to transfer electrons from NADPH for catalytic activity. Cytochrome P450 reductase serves as the redox partner for mammalian P450s; it accepts electrons from NADPH through its flavin adenine dinucleotide (FAD) moiety and donates electrons to P450 through its flavin mononucleotide (FMN) moiety [81–83]. Another redox partner protein, cytochrome *b5*, may enhance catalytic activity for certain mammalian P450s [84]. P450s frequently involved in human drug metabolism include CYP1A1, CYP1A2, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4, and CYP3A5, which differ in tissue localization and substrate selectivity [85]. P450s are expressed in many mammalian tissues, with the highest expression in the liver, gastrointestinal, and respiratory tracts [86]. Major biological roles for the P450s include xenobiotic metabolism, steroid biosynthesis, vitamin metabolism, eicosanoid metabolism, and fatty acid oxidation [87].

The P450 catalytic cycle is a multistep process shown in Fig. 7.8 [80,88,89]. The cycle is initiated by substrate binding to the P450. Substrate binding displaces water as a heme ligand, changing the spin state of the heme iron, thereby allowing for easier reduction of the heme for many P450s [90,91]. An electron from NADPH is then introduced to the P450 through transfer via P450 reductase. Binding of molecular oxygen to the P450 heme is followed by introduction of a second electron to form a nucleophilic ferric peroxo intermediate [92]. This intermediate may continue through the catalytic cycle or lose superoxide in a shunt (nonproductive) pathway. Subsequent protonation of

Figure 7.8 P450 catalytic cycle.

the distal oxygen results in an electrophilic ferric hydroperoxide intermediate [93–95]. The ferric hydroperoxide intermediate may continue through the catalytic cycle or lose hydrogen peroxide in a shunt pathway if the proximal oxygen is protonated. Protonation of the distal oxygen results in a species that rapidly undergoes heterolytic cleavage of the oxygen–oxygen bond to form a reactive iron–oxygen species, compound I [96]. Compound I may then react with substrate to form product or produce water via a shunt pathway through the introduction of two additional electrons and protons. While the general catalytic cycle applies to all P450-mediated reactions, specific reaction mechanisms are dependent on the functional groups present within the substrate.

7.2.1.1 Aliphatic Oxidation. P450s catalyze a variety of biotransformations (Fig. 7.9); common types of P450-mediated oxidations include hydrocarbon oxidation [97], olefin oxidation [98], aromatic hydroxylation [99], and heteroatom oxidation and dealkylation [100]. P450-mediated hydrocarbon oxidation is believed to proceed through a hydrogen atom abstraction (HAT) mechanism, where a hydrogen atom is abstracted from the substrate, followed by oxygen rebound to form a hydroxylation product (Fig. 7.10) [97]. Evidence for a HAT mechanism include a large isotope effect (typically >10) [101], partial stereochemical scrambling [102], and observed allylic rearrangement products [103].

Radical clocks have been used to assess the lifetime of radical intermediates and the rate of the oxygen rebound step [104]. Cyclopropyl groups are often used as radical clocks; radicals formed next to cyclopropyl rings may rearrange to homoallylic radicals that produce ring-opened products if the rate of rearrangement is faster than oxygen rebound or produce cyclopropyl carbinyl products if radical recombination is faster than rearrangement (Fig. 7.11). Adding ring strain to the cyclopropyl group increases the speed of rearrangement [105]. On the basis of experiments using radical clocks, rates for radical recombination during the oxygen rebound step of P450-mediated catalysis

Figure 7.9 Generic examples of P450-mediated biotransformations.

Figure 7.10 Example of the proposed hydrogen atom transfer mechanism.

vary from $1 \times 10^{10} \text{ s}^{-1}$ to those exceeding the theoretical rate constant of $2 \times 10^{12} \text{ s}^{-1}$ for highly strained radical clocks [106]. While higher ratios of rearranged products to carbonyl-derived products were expected from experiments using highly strained radical clocks, product formation ratios indicated that the rate of radical recombination generally increased in a compensatory fashion with radical rearrangement [107]. This finding suggests that P450-mediated hydrocarbon oxidation may proceed by a more complex mechanism than a simple radical recombination. Results observed from the radical clock experiments may be explained by a two-state reactivity model, with a low spin pathway that resembles concerted oxygen insertion and a high spin pathway that resembles radical recombination [108]. The influence of both substrate and enzyme environment influences which pathway predominates.

7.2.1.2 Olefin Oxidation. Olefins undergo oxidation by P450s to form epoxides, which may hydrolyze to form a diol product (Fig. 7.12). The olefin epoxidation mechanism may proceed through either a concerted or a nonconcerted mechanism. The

Figure 7.11 Example of a cyclopropyl radical clock.

Figure 7.12 Proposed mechanism of P450-mediated olefin metabolism.

retention of stereochemistry on P450-mediated epoxidation suggests a concerted mechanism [109]. However, two pieces of evidence argue against a concerted mechanism. P450-mediated reactions with olefins form heme adducts in addition to epoxide products [110]. Direct addition of epoxides to the P450 did not alkylate the P450 prosthetic heme, suggesting that heme alkylation occurs before epoxidation [111]. Some olefins, such as trichloroethylene, form carbonyl compounds as a result of P450-mediated epoxidation [112]. The epoxides produced from these reactions do not form carbonyl products, suggesting that more than one oxidation pathway is needed to account for product formation. As with hydrocarbon oxidation, the observed results may be described using a two-state model, where closure of the epoxide ring in the low spin state proceeds with a small energy barrier such that the reaction is nearly concerted, while closure of the epoxide in the high spin state occurs with a larger energy barrier that allows for other mechanisms to compete with epoxidation [113].

Oxidation of acetylenes is believed to proceed through an oxirane intermediate (Fig. 7.13), which rearranges through shift of a terminal hydrogen to a ketene intermediate [114]. Evidence for this mechanism comes from the observed isotope effect, which suggests that deuterium migration occurs in the rate-limiting step as oxygen is transferred to the acetylene [115].

7.2.1.3 Aromatic Oxidation. Hydroxylation of aromatic rings proceeds through an arene oxide intermediate (Fig. 7.14) [99]. Formation of the arene oxide intermediate is

Figure 7.13 Proposed mechanism of P450-mediated acetylene metabolism.

Figure 7.14 Proposed mechanism of P450-mediated aromatic oxidation.

followed by hydrogen migration in a process called an *NIH shift* [116]. Alkyl or halogen groups may also migrate, depending on the substrate [117]. The phenol product results from tautomerization. Evidence to support this mechanism includes partial retention of the shifted hydrogen and a small inverse secondary isotope effect for the reaction [118]. Since the NIH shift is not the rate-limiting step, the reaction is not sensitive to primary isotope effects. Hydroxylation of phenyl rings with adjacent cyclopropyl groups proceeds without ring opening, suggesting that a discrete radical mechanism is not favored for arene oxidation [119].

7.2.1.4 Heteroatom Dealkylation and Oxidation.

7.2.1.4.1 N-Dealkylation. Tertiary amines are metabolized predominantly through dealkylation, which can occur through various peroxidases, but the most common pathway for dealkylation is by the cytochrome P450 superfamily (Fig. 7.7). As such, a significant effort has been put forth to understand the mechanism of cytochrome P450 N-dealkylation reactions. The two predominant mechanisms in the literature are illustrated in Fig. 7.15. Mechanism A is that of single-electron transfer (SET) and mechanism B is that of HAT. For SET, the initial step is envisioned to occur by electron transfer from the amine nitrogen to the high valent iron oxene species forming a cation radical intermediate, which is then capable of catalyzing deprotonation of the ammonium radical followed by oxygen rebound to form the hydroxylamine [120]. Decomposition of the carbinolamine intermediate yields the N-dealkylated product.

Figure 7.15 Proposed mechanisms for P450-mediated N-dealkylation: (i) single-electron transfer (SET) and (ii) hydrogen atom abstraction (HAT).

Alternatively, for HAT, a hydrogen atom is abstracted directly from the α -carbon followed directly by radical recombination to form the α -hydroxylamine. Differentiating between the two mechanisms has been explored extensively.

Kinetic isotope effects have been employed to differentiate between the two mechanisms. Initial interrogation of P450 N-dealkylation with selectively deuterated analogs such para-substituted *N,N*-dimethylanilines produces small kinetic isotope effects ($k_H/k_D < 4$). In contrast, alternate enzyme systems such as horseradish peroxidase (HRP) where SET is considered the mechanism of oxidation result in isotope effects that approximate the theoretical maximum. By comparison, HAT is the accepted mechanism for alkane hydroxylation which produces maximal kinetic deuterium isotope effect values ($k_H/k_D > 7$). The small isotope effects observed with *N,N*-dimethylaniline are consistent with hemeprotein catalyzed demethylation reactions that involve a deprotonation step [120]. However, small isotope effects have been demonstrated for demethylation of trimethylamine by *tert*-butoxy radical [121]. Dinnocenzo *et al.* [122] also observed a small isotope effect for hydrogen atom abstraction from *N,N*-dimethylaniline by *tert*-butoxy radical. The smaller observed isotope effects have been rationalized by the proposed weakening of the α -C–H bonds present in amines which facilitate a relatively early transition state. Nonsymmetrical transition states as described by the Westheimer kinetic postulate would produce an isotope effect below the theoretical maximum (Fig. 7.16). These contradicting results indicate isotope effect data alone may not be sufficient to distinguish the mechanism of P450 N-demethylation [123].

Synthetic heme mimetics and chemically designed metabolic probes have been employed to examine HAT (*tert*-butoxy radical) and SET (cation radical deprotonation) mechanisms in comparison to metabolites obtained directly from NADPH-supported P450 reactions. The combination of isotope effects with substituent effects has been used to generate isotope effect profiles for exploring reaction mechanisms. The increased number of compounds allows for trends to be explored in the resultant data to provide increased confidence in interpretation of reaction mechanism across different reaction systems. For example, P450 reactions revealed most similarity to *tert*-butoxy radical model supporting HAT as the mechanism for N-dealkylation (Fig. 7.17). The

Figure 7.16 Example of asymmetrical and symmetrical transition state corresponding to theoretical difference in kinetic isotope effects: (a) early transition state $k_H/k_D > 4$ and (b) symmetrical transition state $k_H/k_D \sim 8$.

Figure 7.17 Isotope effects by *tert*-butoxy radical (HAT mediated) compared to P450-supported reactions. Plot includes accepted HAT pathways (xylene, toluene, and benzyl alcohol) in addition to several substituted *N,N*-dimethylanilines.

concordance between *tert*-butoxy radical and P450-supported reactions further support HAT mechanism for P450 reactions.

Chemical probes have been designed and synthesized to interrogate the mechanism of *N*-dealkylation. As described earlier in this section, radical clocks can differentiate oxidative mechanisms based on product ratios. A series of *N*-cyclopropyl anilines have been designed to evaluate different product ratios as a tool to rationalize HAT versus SET [105,124–126]. In principal, the rapid ring opening associated with *N*-cyclopropyl ring of the nitrogen cation radical would favor the *N*-decyclopropylation. However, the major pathway favored *N*-demethylation in support of HAT as the mechanism for oxidation (Fig. 7.18) [124]. Alternatively, Atkinson *et al.* [105] utilized a similar probe but in contrast yielded results supportive of the SET mechanism.

Figure 7.18 Example of product ratios from radical clock experiments with HRP and P450.

N-Oxides or *N*-hydroxyl products can also be catalyzed by P450s. The reaction is generally thought to proceed through the formation of a radical cation. The mechanism of partitioning between *N*-oxide and *N*-dealkylation remains unclear. Instability and potential for reduction of *N*-oxide may limit the extent of P450 *N*-oxide formation. The ability for *N*-oxides to back donate the oxygen to P450 was exploited in the form of synthesis of various deuterated *N*-oxide probes in order to specifically investigate the potential for high valent iron oxene to catalyze *N*-dealkylation reactions [127]. Specifically, the *N*-oxides for a series of para-substituted $^{13}\text{C}_2\text{H}_2$ -labeled *N,N*-dimethylanilines were synthesized with the intent to function as both substrates and surrogate oxygen atom donors. This particular substrate probe isolates the high valent iron oxene in the P450 catalytic cycle on reduction of the *N*-oxide to the iron–porphyrin complex. Coupled with deuterium isotope effect profiles obtained using the *N*-oxide system were found to closely match the profiles produced using NAD(P)H/NAD(P)-P450 reductase/ O_2 system.

7.2.1.4.2 O-Dealkylation. Oxidative O-dealkylation represents significant phase I oxidation pathway. O-Dealkylation reactions catalyzed by P450 enzymes have been studied using primary deuterium and tritium isotope effects to estimate the intrinsic isotope effect for this reaction using the technique of Northrop [128]. The large intrinsic isotope effect ($k_{\text{H}}/k_{\text{D}} > 7$) is consistent with a linear transition state on hemiacetal formation in which little to no bonding exists between the α -carbon and the hydrogen atom (Fig. 7.16) [128]. These results are consistent with hydrogen abstraction mechanism put forth by Groves and McClusky [97] for aliphatic oxidation. In addition, ^{18}O experiments illustrate that heavy water is incorporated into the metabolite byproduct [97]. Evidence for O-dealkylation to proceed through HAT is also provided by Dowers and Jones [129], wherein they designed and utilized quinoline analogs as evidence for HAT.

P450-mediated reactions follow the general reactivity pattern of *N*-dealkylation > benzylic hydroxylation > O-dealkylation > aliphatic hydroxylation > ω -hydroxylation [130]. These results correlate well with quantum mechanics-based AM1 calculations

of the stability and ionization potential of the radical resulting from HAT. These efforts have been extended to include aromatic oxidations through parameterization of the HAT and aromatic oxidation pathways based on experimentally determined regioselectivity data [131].

7.2.2 Flavin Monooxygenase

Mammalian flavin-containing monooxygenases (FMOs) are able to metabolize a variety of structurally diverse xenobiotics [132]. The structural requirements for FMO oxidation reactions (Fig. 7.19) are relatively straightforward as the substrate requires a soft nucleophile, usually a nitrogen or sulfur heteroatom but in rare cases may also include carbon, phosphorus, or selenium [133–138]. Interestingly, while nucleophilicity is the principal driver for FMO oxidations, structure–activity studies suggest that size and charge of potential substrates are important factors that mediate access to the enzyme’s active site [139,140]. As a consequence, the mechanism of FMO oxidation reactions are all similar and observed differences in the substrate specificities across the family of enzymes are all nearly due to differences in the active-site topography and access to the oxygenating species [141,142]. The influence of active-site topography on substrate oxidation is particularly evident in terms of the stereoselectivity observed with many

Figure 7.19 (a) Generic mechanism of FMO oxidation reaction. (b) Examples of FMO metabolism reactions with voriconazole and sulindac.

FMO oxidation reactions [143,144]. In the 1980s, Walsh and coworkers examined the stereochemistry of sulfoxidation of ethyl *p*-tolyl sulfide by hepatic microsomal FMO and found that the enzyme-catalyzed formation of the (R)-enantiomer of ethyl *p*-tolyl sulfoxide in great enantiomeric excess [145,146]. In this fashion, topography of the enzyme's active site not the substrate dictates the final chirality of the product as the enantiotopic electron pairs on the sulfur atom of an asymmetrically substituted sulfide are equivalent. Restated, chemical reactions that utilize peroxides or peracids as oxidants in solution proceed with no stereochemical preference and thus generate racemic sulfoxides [147]. However, in the chiral environment of the enzyme's active site, the electron pairs are not equivalent and stereoselective sulfoxidation can, and often times does, occur.

As with many biological oxidation reactions, the catalytic cycle for FMO enzymes is complex and involves several steps (Fig. 7.20). The underlying catalytic feature of this class of enzyme is their ability to stabilize a flavin-hydroperoxide intermediate [148,149]. Unlike the cytochromes P450 [150], the FMO peroxy intermediate has been found to be stable for minutes to hours at 4°C and can be observed spectrally [151].

Figure 7.20 Proposed FMO catalytic cycle.

In the first step of the FMO catalytic cycle, FAD undergoes two-electron reduction by NADPH [152,153]. Chemistry of NADPH requires that reduction of the flavin cofactor is facilitated through a hydride transfer from the C4 atom of the nicotinamide ring to the flavin N5 atom (Fig. 7.20a) [154,155]. The reduced flavin reacts rapidly with molecular oxygen to form the stable peroxyflavin intermediate that is able to wait for a suitable nucleophile with which to react [156,157]. Stabilization of the intermediate requires the presence of NADP^+ [158], which remains tightly bound to the enzyme throughout the catalytic cycle [159]. It has been proposed through computer simulation of FMO active that NADP^+ is able to shield the enzyme's active site (Fig. 7.20b), and thus provide proper H-bonding environment, which in turn promotes a prolonged half-life to the peroxyflavin intermediate [160]. The binding of oxygen is followed by the nucleophilic attack by the substrate on the peroxyflavin, which results in one atom of molecular oxygen being transferred to the substrate (Fig. 7.20c). Following metabolite release, the resulting flavin hydroxy psuedobase is converted to FAD via the loss of water (Fig. 7.20d). It should be noted that the release of water and subsequent regeneration of FAD is a rate-limiting step in the FMO cycle [141]; thus, unlike the cytochrome P450 cycle [161], substrate binding has little influence on the rate of catalysis. The final step in the FMO catalytic cycle is the release of NADP^+ , which regenerates the FMO FAD moiety (Fig. 7.20e).

7.2.3 Aldehyde Oxidase

Aldehyde oxidase (AO) and xanthine oxidase (XO) are cytosolic members of the molybdenum hydrolase family. Both enzymes are capable of oxidizing aldehydes and nitrogen-containing aromatic compounds. While the scope of AO/XO involvement in xenobiotics remains somewhat limited relative to P450s, their role in the clearance of new drugs is likely to see an increase based on several factors [162,163]. The desire to reduce P450 clearance leads to increase number of heteroaromatic rings, a primary pharmacophore feature of AO/XO substrates. The awareness of AO/XO in drug metabolism has increased the availability of recombinant enzymes and selective chemical inhibitors for characterization of AO/XO metabolism. For example, planar nitrogen-containing heteroaromatic systems serve as the primary pharmacophore associated with competitive inhibitors of ATP-binding site for kinases that may coincide with AO/XO contributing to the clearance of these xenobiotics [164].

In accord with attempts to reduce P450 metabolism, the addition of nitrogens into aromatic ring systems is often attempted. The added nitrogens decrease the electron density of the carbon atoms in the heterocycle and tend to reduce P450 metabolism [127]. However, the reduced electron density of the carbon atoms in the heterocycle increases the potential for nucleophilic oxidation by AO/XO [165]. Both XO and AO enzymes contain molybdenum pyranopterin cofactors (MoCo) that facilitate nucleophilic oxidation of electron deficient substrates [166]. Most commonly, the oxidation occurs adjacent to the nitrogen in a heterocycle. The active sites are speculated to have similar structure capable of oxidizing a variety of dissimilar structures possessing significant overlap of substrates between AO/XO [165]. Catalysis involves cleavage of C–H bond and the oxygen incorporated into product arises from water and the byproduct of the oxidative step are superoxide and hydrogen peroxide [167]. A depiction of the catalytic mechanism for AO/XO metabolism is shown in Fig. 7.21. The oxidation has been demonstrated to occur through the formation of a tetrahedral transition state [168].

Figure 7.21 Proposed mechanism for AOX-mediated metabolism.

Several substrates and inhibitors exist for AO/XO, which can be helpful in distinguishing the enzymes involved in metabolism. XO is specific for the conversion of 1-methylxanthine to 1-methyluric acid, which are secondary metabolites of caffeine [169] (Fig. 7.22). Allopurinol is metabolized by XO to oxypurinol, which forms an inhibitory complex with the reduced form of the enzyme (Fig. 7.22) [170]. On reoxidation, the inhibition of oxypurinol is diminished [171]. FYX-051 also forms a tetrahedral complex and functions as structure-based inhibitor of XO [172]. In contrast, febuxostat does not complex to the molybdenum center but blocks substrate access directly [173,174]. Several compounds including hydralazine, chlorpromazine, and isovanillin were identified as reasonably selective inhibitors of AO after screening a panel of 239 drugs for AO inhibition [162].

AO/XO have also been exploited for the purpose of converting prodrugs to active drug species in order to overcome ADME-related issues. For example, 5-fluorouracil (5-FU) is a generic antineoplastic, which is rapidly metabolized in the gastrointestinal tract limiting the bioavailability of 5-FU [175]. In order to overcome this obstacle, a prodrug form, 5-fluoro-pyrimidinone, was employed, whereby the keto group is introduced by hepatic AO after absorption [176]. Another example is that of the antiviral penciclovir, which displays poor oral absorption [177]. The diacetyl 6-deoxy prodrug derivative of penciclovir, famciclovir, displays improved absorption and systemic availability [178].

Predictions of AO metabolism have been studied using density functional theory to qualitatively determine the site(s) of oxidation based on the analysis of the energetics of the proposed tetrahedral intermediate with the oxidized carbon [165]. In general, it has been suggested the AO metabolism will occur at the most electropositive carbon in a molecule with some influence on regioselectivity determined by steric bulk

Figure 7.22 Example reactions catalyzed by AOX.

[179]. Additional factors must play a role in metabolite regioselectivity as illustrated by the fact that the most electropositive carbon is not always the site of metabolism. The DFT calculations from Torress *et al.* suggest that oxidation of substrates by AO appears reliant on the electronic effects of the substituents. The use of 6-substituted quinazolinones demonstrate the electronic effects and increase in reaction rates with increased electron-withdrawing groups at the 6-position [180,181]. The calculated results provide a rank ordering of potential products by evaluating the individual tetrahedral intermediates precluding metabolite formation. For the compounds examined, >90% of AO metabolites were correctly predicted. The calculations were also able to differentiate the metabolites generated by XO compared to AO for a series of closely related molecules.

7.2.4 Monoamine Oxidase

Mammalian monoamine oxidases (MAOs) are flavin-containing enzymes that catalyze the oxidation of amines to aldehydes (Fig. 7.23) [182,183]. Two isozymes are known, MAO-A and MAO-B, which differ in substrate and inhibitor selectivity [184]. MAOs are expressed in many mammalian tissues, with high expression in both the liver and placenta [185]. MAOs are also present in the brain; they are believed to have an important biological function for the inactivation of neurotransmitters [186].

The requirements for MAO oxidation are a basic nitrogen and an adjacent carbon with two α -hydrogens (Fig. 7.24). The substrate-binding region is a flat cavity lined with hydrophobic residues [187]. Structure–activity relationships (SARs) suggest that

Figure 7.23 Example of MAO metabolism reactions with dopamine.

Figure 7.24 MAO catalytic cycle.

Figure 7.25 Proposed mechanisms of MAO-mediated reactions: single-electron transfer and hydrogen atom abstraction.

the size and shape of potential substrates determine access to the enzyme's active site [188]. The mechanisms of MAO-catalyzed reactions are generally similar; therefore, differences in observed kinetics are due to specific interactions between the enzyme and the substrate [189]. The influence of active-site topography is particularly important due to the stereochemical requirements for MAO oxidation. In the 1980s, Yu and coworkers found that the pro-(*R*)-hydrogen of MAO substrates was lost exclusively based on the reactivity of stereoselectively deuterated dopamine analogs [190,191]. In this sense, the active site dictates reaction stereochemistry. However, the aldehyde moiety resulting from substrate oxidation is not chiral, such that MAOs do not produce an inherently chiral product.

MAO-mediated oxidation has been proposed to proceed by three mechanisms: SET [192], HAT [193], and a polar/covalent mechanism (Fig. 7.25) [194]. The SET mechanism begins with transfer of an electron from the substrate nitrogen, forming an aminyl radical cation and a flavone semiquinone radical. Loss of an α -hydrogen creates a carbon-centered radical, which can then transfer an electron to form an iminium ion and a flavone semiquinone. On the basis of the results of SAR studies, the reactive carbon is positioned in front of the N5-C4a locus, with its α -hydrogens located ~ 3.6 Å from the flavin N5. The iminium ion is released from the active site and undergoes hydrolysis to form the aldehyde product. The HAT mechanism proceeds through a similar pathway, but begins with direct loss of an α -hydrogen. In the polar/covalent mechanism, the substrate forms a covalent bond with FAD (Fig. 7.26). Cleavage of the bond results in formation of an iminium ion and FADH₂.

Figure 7.26 Proposed polar/covalent mechanism for MAO-mediated reactions.

MAO-A and MAO-B differ in both inhibitor and substrate selectivity. Substrates for MAO-A include 5-hydroxytryptamine and epinephrine; clorgyline is a selective inhibitor of MAO-A [195]. Substrates for MAO-B include benzyl amine and β -phenylethylamine; deprenyl is a selective inhibitor of MAO-B [196]. Differences in substrate selectivity may partially be explained by a smaller entrance cavity for MAO-B, although results from site-directed mutagenesis studies suggest that the Tyr326Ile MAO-B mutation conferred MAO-A activity and the Ile335Tyr MAO-A mutation conferred MAO-B activity [197].

7.2.5 Carboxylesterase

Carboxylesterases (CEs) metabolize and eliminate endogenous and xenobiotic esters. In humans, the highest hydrolase activity is found in the liver [198–200]. The mechanism for catalysis is similar to that of other α/β hydrolases that employ an active-site serine, histidine, and acidic (glutamic or aspartic acid) residue that are spatially oriented to form a catalytic triad (Fig. 7.27) [198,201–204]. The general mechanism occurs in two steps: first, the serine hydroxyl forms an acyl intermediate with the substrate. The acyl intermediate is then hydrolyzed to form a product. Like other drug-metabolizing enzymes, CEs display broad substrate specificity mediating the hydrolysis of esters, amides, and thioester substrates (Fig. 7.28) [205,206]. CEs have also demonstrated the ability to transesterify compounds such as cocaine, methylphenidate, and meperidine [207,208]. The inhibition of CEs has attracted attention as a mechanism of therapeutic intervention or modulation of coadministered prodrugs [209–211]. Furthermore, inhibition of CE is a primary off-target concern for therapeutics aimed toward inhibiting other esterase and hydrolase enzymes [212]. Differences in catalytic efficiencies have been observed when comparing human CE to CE found in preclinical species [199,213]. The mechanistic understanding of CE in drug metabolism has been established through a variety of techniques including ligand-based SAR, crystallography, and site-directed mutagenesis studies.

The strategically positioned amino acids for hydrolysis combined with the observed substrate promiscuity presents a unique dichotomy. One explanation is that CE displays significant induced fit of protein that is predicated on the proper spatial orientation of the substrate [214]. On substrate induced fit, the conformation of the catalytic triad

Figure 7.27 The catalytic triad binding methylphenidate to form tetrahedral transition state complex.

is postulated to form a strong hydrogen bond also known as a *low barrier hydrogen bond* between the catalytic His and acidic residue to yield an increased reactivity of His as a general base [215–217]. As might be expected, subtle changes in chemical structure of substrates and inhibitors can have a profound impact CE activity. For example, a series of cypermethrin analogs were examined to understand the role of stereochemistry on CE catalysis. Huang *et al.* [218] demonstrated a >20-fold difference in specific activity between *cis*- and *trans*-cypermethrin analogs. CE is the major first-pass enzymatic pathway for methylphenidate with higher activity toward the

Figure 7.28 (a) Hydrolysis of cocaine ester, (b) hydrolysis of CPT-11 to bioactive SN-38, and (c) amide hydrolysis of isocarboxazid.

L-isomer compared to the D-isomer [219]. The stereochemistry leads to a subtle change in orientation of enzyme–substrate complex leading to profound changes in catalytic efficiency. This may be expected for CE based on the specific distance requirements for all three residues to act in concert with one another. The activity of the potent anti-cancer drug CPT-11 requires activation by hCE (Fig. 7.28). CPT-11 is the carbamate prodrug of the active SN-38 hCE-derived metabolite [206,220]. The conversion, however, is relatively inefficient where typically <5% of CPT-11 is converted to SN-38 [221]. Additional characterization of CE active site has been established with various competitive inhibitors. Trifluoromethyl ketones (TFKs) represent a class of compounds that display some of the most potent inhibitors of CE [222]. In general, the potency of TFK analogs is attributed to the enhanced electrophilicity of carbonyl carbon as a result of the electron-withdrawing nature of the CF_3 moiety (Fig. 7.29). In addition, TFK inhibitors also bind in the favored conformation of the transition state as a tetrahedral intermediate and thus are termed *transition state analog inhibitors*. Wheelock *et al.* [222] nicely demonstrated that TFK analogs were more amenable to mimicking the transition state through the formation of the gem diol (sp^3 hybridized conformation; tetrahedral intermediate common to CE transition state), which lead to improved inhibitory potencies (Fig. 7.29). Other inhibitors include organophosphorus compounds, which also exploit the nucleophilic behavior of the catalytic serine to form an irreversible covalent acyl enzyme intermediate with compounds such as soman and tabin

Figure 7.29 General structure of TFK inhibitor analogs where trifluoro substitution increase electrophilicity of carbonyl carbon favoring gem diol formation.

[223,224]. Interestingly, hCE does not seem to readily form the irreversible complex formed in rCE.

Site-directed mutagenesis of hCE identified key portions of the protein for substrate and metabolite entrance and exit channels from the active site [225,226]. Rational enzyme design was accomplished with site-directed mutagenesis studies in combination with crystal structure data to develop an hCE mutant with CPT-11 activity similar to that achievable with rCE. Modification of eight amino acids demonstrated improved CPT-11 hydrolysis, which was proposed to occur via an increased flexibility of the active-site cavity necessary to bind CPT-11.

The crystal structure of hCE in complex with the potent inhibitor benzil (45 nM) demonstrated the formation of covalent product [227]. Crystallization with modest inhibitor tamoxifen revealed binding at the α -site of the protein where in this may partially explain the partial inhibition properties of tamoxifen and provide evidence that the α -site may serve as an access channel for different substrates [227].

7.2.6 Epoxide Hydrolase

Mammalian epoxide hydrolases (EHs) catalyze the conversion of three-membered cyclic ethers, called *epoxides*, to diols (Fig. 7.30) [228]. EHs are expressed in many mammalian tissues with the highest concentrations found in the liver [229,230]. Several EHs are present in mammals; however, microsomal epoxide hydrolase (mEH) and soluble epoxide hydrolase (sEH) have been the focus of research efforts [231]. They differ in both subcellular localization and substrate specificity. mEH is found within the endoplasmic reticulum and metabolizes xenobiotic-derived epoxides [232]. sEH is found in the cytosol and metabolizes endogenous fatty acid epoxides [233]. The biological role of mEH is the detoxification of xenobiotics [234], while sEH appears to play a role in the hyperpolarization of vascular smooth muscle by controlling the levels of vasodilatory epoxyeicosatrienoic acids [235,236].

Figure 7.30 Example of EH metabolism reaction with linoleic acid epoxide.

Metabolism by EH requires the presence of an epoxide. The mechanisms of EH-mediated hydrolyses are similar; therefore, differences in observed kinetics are generally due to specific interactions between the enzyme and a potential substrate. SARs suggest that both the size and shape of a substrate are key factors in mediating access to the EH active site [237]. The active site of sEH contains a 25-Å long, L-shaped hydrophobic domain at the C-terminus where substrates bind for catalysis [231]. The influence of active-site topography on epoxide hydrolysis is particularly evident with regard to the stereoselectivity observed with many EH reactions. In the 1990s, Zeldin and coworkers [238] examined the stereochemistry of the conversion of *cis*-epoxyeicosatrienoic acids to diols by hepatic sEH and found that incubations containing the 8,9- or 14,15-epoxides formed diols stereoselectively, while incubations containing the 11,12-epoxide were not stereoselective. In this fashion, both the topography of the EH active site and the shape and orientation of the substrate within the EH active site influence the final stereochemistry of the product.

The catalytic cycle for EH is complex and involves several steps (Fig. 7.31). An underlying feature of this enzyme class is a catalytic triad containing a nucleophilic acid (usually Asp), an orienting acid (Asp or Glu), and a basic histidine [228]. In the first step of catalysis, polarization of the epoxide moiety by tyrosines located on the

Figure 7.31 EH catalytic cycle.

top of the EH active site occurs concurrently with nucleophilic attack on an epoxide carbon by an acidic residue located on the opposite side of the active site [239]. This attack occurs preferentially at the least sterically hindered or most reactive carbon of the epoxide. Attack by the nucleophilic acid is aided and directed by a nearby histidine-orienting acid pair [240]. Ring opening of the epoxide results in formation of a covalent ester bond between the attacking acid and a carbon from the epoxide. This intermediate has been termed the *hydroxyl alkyl-enzyme intermediate* [228]. A water molecule, activated by the histidine-orienting acid pair, reacts with the hydroxyl alkyl-enzyme intermediate to release the enzyme and a diol as products.

Evidence for the mechanism of catalysis and the presence of a hydroxyl alkyl-enzyme intermediate comes from three sources. In a single turnover experiment using 1,10-phenanthrene-5,6-oxide as substrate, transfer of ^{18}O from hepatic mEH to the substrate was best explained through formation of a hydroxyl alkyl-enzyme intermediate [241]. Inhibition kinetics of EH-mediated reactions were well described using models based on formation of a covalent enzyme-inhibitor intermediate, whose half-life is inversely proportional to inhibition potency [242]. Additionally, a covalent adduct of hepatic mEH and $[1-^{14}\text{C}]$ epoxystearic acid was detected after denaturing SDS gel electrophoresis [243]. Formation of the adduct was inhibited in the presence of 1,1,1-trichloropropylene oxide, an inhibitor of mEH.

7.2.7 Ketoreductase

The aldo-keto reductases (AKRs) comprise a superfamily of monomeric (monomer molecular weight = 34–37 kDa), NADPH-dependent oxidoreductases with similar physical and chemical properties [244]. Much more is known about the physiological roles of carbonyl-reducing enzymes (e.g., steroid and prostaglandin metabolism, housekeeping, and stress response) than their roles in drug metabolism [245]. With respect to drug metabolism, typically the AKR enzymes catalyze the reduction of aldehydes and ketones to the corresponding alcohol products (Fig. 7.32) and the subsequent products often times undergo further conjugation and elimination [246]. For example, AKRs play an important role in the metabolism of the therapeutic agent such as haloperidol, ketotifen, and oracin [247–249]. In humans, an important pathway of warfarin metabolism is reduction of the ketone to a secondary alcohol [250]. This reaction is catalyzed by cytosolic ketone reductases and is stereospecific, producing only the (S)-enantiomer of warfarin enantiomers [251].

A nomenclature system to group AKRs has been adopted and currently 14 subfamilies have been identified [252]. However, only four AKR subfamilies, namely, 1A, 1B, 1C, and 7A, have documented roles in xenobiotic carbonyl metabolism [253]. To date, over 15 crystal structures of AKRs complexed with their ligands have been determined [254]. In each instance, the AKR structure reveal a $(\alpha/\beta)_8$ -folding pattern (triose isomerase or TIM barrel fold), where the central β -strands form the staves of a barrel, with large loops at the back that form the ligand-binding site [255]. The cofactor-binding site and the active site are highly conserved across the superfamily. The active site (Fig. 7.33) contains a conserved catalytic tetrad (Tyr, Asp, Lys, and His), which forms an oxyanion-binding site with the nicotinamide ring of the cofactor via a hydrogen bonding network [256–258]. In contrast, strong variation exists in the structure of the substrate-binding cavity, which is largely defined by the residues from the loops [259]. The reaction mechanism for this class of enzymes has been studied in

Figure 7.32 (a) Generic mechanism of ketone reduction. (b) Examples of AKR metabolism reactions with haloperidol and warfarin.

detail, revealing an ordered bi-bi mechanism [260], where the cofactor binds first and leaves last [261]. Interestingly, while the catalyzed reaction favors alcohol formation, it is possible for the reverse reaction to occur, albeit to a limited extent.

Figure 7.33 Proposed AKR active-site hydrogen bonding network to form the oxyanion-binding site with the nicotinamide ring in ketone reduction reaction.

A common feature of the carbonyl-reducing enzymes is their proposed two-electron reduction mechanism involving hydride transfer from the cofactor to the carbonyl carbon, which is facilitated by general acid [262]. In this fashion, unsymmetrical ketones generate chiral centers on reduction to alcohols. As a consequence, for many substrates, the stereoselectivity of carbonyl reductase-catalyzed ketone reduction is dependent on the steric situation of substrates and may be predicted with “Prelog’s rule” [263]. Prelog’s rule describes the reduction of ketone to yield optically active secondary alcohols. In this instance, the chirality of an alcohol arising from nucleophilic addition to a ketone depends on which prochiral face accepts the nucleophile and the sequence priority of the nucleophile relative to other substituents of the carbonyl function [264]. In hydride transfer reactions, the hydride nucleophile will always be the lowest priority group; thus, the reface addition of the hydride to a ketone will always generate an S-configuration alcohol [265].

7.3 PHASE II DRUG METABOLISM REACTIONS

7.3.1 Glucuronosyltransferase

The UGT family of enzymes catalyzes the conjugation of a glucuronic acid moiety from uridine diphosphoglucuronic acid (UDPGA) to a broad range of substrate molecules (Fig. 7.34) [266,267]. The glucuronidated compounds are more hydrophilic than their aglycone counterparts and thus more readily excreted from the body. Any functional group with sufficient nucleophilicity can be an acceptor for the glucuronic acid transfer, with the most common functional groups including phenols, aliphatic alcohols, carboxylic acids, amines, thiols, and nucleophilic carbon atoms [51]. Common substrates include endogenous compounds such as bilirubin, estrogens, and fatty acids as well as numerous xenobiotics.

Figure 7.34 Example of UGT metabolism reaction with estradiol.

Figure 7.35 Proposed mechanism of UGT-catalyzed glucuronidation.

It is now generally accepted that UGT-catalyzed glucuronidation proceeds via an acid–base mechanism similar to that exhibited by serine hydrolases [268,269]. A conserved histidine residue serves as a catalytic base to deprotonate a nucleophilic site on the aglycone molecule, which then results in a nucleophilic substitution at the C1 atom of the glucuronic acid moiety. Consequently, the protonated histidine residue is stabilized through an interaction with a proximal aspartic acid residue that is also conserved across human UGTs (Fig. 7.35). The nucleophilic attack on the C1 carbon occurs through an S_N2 reaction mechanism with stereoinversion from the α -configuration at the C1 carbon of the glucuronic acid moiety in UDPGA to the β -configuration in the resulting glucuronide [270]. The reaction mechanism is supported by data showing a correlation between reaction rates and nucleophilicity for a series of phenol-containing compounds [271]. The order in which the aglycone and UDPGA bind during the UGT-catalyzed S_N2 reaction remains ambiguous and may be isoform dependent, with proposed mechanisms including a compulsory-ordered bi-bi mechanism, a random-ordered bi-bi mechanism, or a Theorell–Chance reaction mechanism [271–278].

A unique scenario exists following a nucleophilic attack on the C1 carbon by a carboxylic acid moiety. The resulting acyl glucuronides are more reactive than ether-linked glucuronides and present the possibility for additional reaction steps, where the aglycone migrates via intramolecular transesterification from the C1-hydroxyl group

of the glucuronic acid moiety to the C2-, C3-, or C4-hydroxyl groups [279,280]. All the steps in the migration are reversible, except for the first migration step from the C1 to the C2 position. On migration, acyl glucuronides can covalently adduct proteins and other macromolecules through one of two mechanisms. First, a direct nucleophilic attack on the glucuronic acid moiety by an amino acid residue results in binding of the aglycone to protein through a carbonyl linkage and liberation of D-glucuronic acid [281–285]. The second proposed mechanism for the irreversible binding of acyl glucuronides to protein involves the interaction of a protein nucleophile, such as an internal lysine residue or the N-terminus of a protein, and the free aldehyde of the open-chain glucuronic acid moiety to form an imine bond between the two functional groups. The initial interaction is reversible; however, it can subsequently be followed by an irreversible imine reduction or Amadori rearrangement, which occurs when the aglycone moiety has migrated to the C3 or C4 position, and is converted to the more stable 1-amino-2-keto product [286,287].

In addition to the observed stereochemistry observed at the C1 carbon of UDPGA during glucuronidation, the UGT family of enzymes also has also been shown to exhibit a high degree of stereoselectivity regarding the aglycone acceptor molecules. A recent study aimed at measuring the eudismic ratios of a series of chiral secondary alcohols for UGT2B7 and UGT2B17 demonstrated that the UGTs can display a degree of stereoselectivity that is similar to that generally reserved for highly specific receptor proteins [288]. Similarly, both isoforms have shown substrate specificities that are dependent on the configuration (α vs β) of the 17-hydroxyl group of steroids such as estradiol and testosterone [289,290]. Interestingly, the stereochemistry of the aglycone had a negligible effect on the affinity of the enzyme–substrate complex and thus may reflect the importance of substrate orientation in the transfer of the glucuronic acid moiety. Additional studies have also demonstrated the importance of the orientation of the glucuronic acid, uridine diphosphate, and aglycone groups in forming the ternary UGT-UDPGA-aglycone complex [291].

While substrate selectivities vary across the different UGT isoforms, it is generally accepted that the N-terminal domain plays an important role in substrate recognition [67,268, 292–302]. It has been suggested that a conserved histidine residue is generally required for glucuronidation through proton abstraction, while a proline residue is more likely involved in the glucuronidation of tertiary amines [303]. From the standpoint of the acceptor molecule, compounds that are hydrophobic in nature and contain a nucleophilic site generally make good substrates for glucuronidation. More recently, the effect of chemical substituents within close proximity to the nucleophile on the rate of glucuronidation has been examined. In general, an aromatic ring adjacent to the nucleophilic site appears to greatly increase the likelihood of glucuronidation at the nucleophilic site, possibly through electronic stabilization of the reaction intermediate or through π -stacking interactions within the active site of the enzyme, which serve to decrease the entropy of bond formation between the acceptor molecule and UDPGA [304,305]. It has also been noted that nucleophiles with a more negative partial charge combined with a higher Fukui function (describing the likelihood of electrophilic or nucleophilic attack at a given atom) are more prone to glucuronidation [305]. In addition to the nucleophilicity of the acceptor molecule (aglycone), glucuronidation by hepatic UGTs is also highly dependent on the hydrophobicity of the aglycone, with an optimal octanol–water partition coefficient ($\log P$) of ~ 2 having been reported [306]. Finally, steric interactions can also play a role in substrate selectivity as well as overall

rates of glucuronidation, as has been observed for a series of substituted phenols, where bulky substituents in the ortho-position to the hydroxyl group generally decreased the susceptibility of the nucleophile to glucuronidation [307,308].

7.3.2 Glutathione Transferase

Cytosolic and membrane-bound forms of glutathione-*S*-transferase (GST) are encoded by two distinct superfamilies [309]. The soluble protein form exists as two polypeptide subunits creating dimer with a molecular mass of 50 kDa. GSTs catalyze the transfer of the endogenous tripeptide, GSH to the electrophilic center of a diverse set of substrates to form a polar *S*-glutathionylated reaction product (R-SG). GST subunits contain a GSH-binding site (G-site) and a hydrophobic substrate site (H-site) (Fig. 7.36) [310,311]. On proper orientation of substrate and GSH, the reaction proceeds through the formation of a Meisenheimer complex (Fig. 7.37).

The G-site binds GSH extending the tripeptide in a conformation that points the sulfur toward the subunit in which it is bound. Electrostatic interactions with the glycine of GSH are favorable with the subunit it binds ($K_d = 20 \mu\text{M}$). The spatial orientation of GSH in the active site is conserved across soluble forms of GST. However, the interactions stabilizing the GSH-GST subunit complex are unique to the isoform and isoform-specific interactions may contribute to differences in conjugate regioselectivity and catalytic activity of the different enzyme forms [312]. Ultimately, GSH binding at the G-site lowers the activation energy for the nucleophilic attack by reducing the thiol pK_a of GSH. The thiol pK_a of unbound GSH is 9.0 ($\text{GSH} \rightarrow \text{GS}^-$ in water) compared to GSH in complex with GST subunit where the pK_a is 6.0–7.5 [313–315]. A shift

Figure 7.36 General binding site for GSH (G-site) and electrophilic substrate (H-site). (See color insert.)

Figure 7.37 Meisenheimer complex formation with CDNB.

in pK_a of that magnitude requires ~ 3 kcal/mol of energy, which is generated through the binding of GSH at the G-site.

The H-site is composed of the C-terminal domain and displays greater primary sequence diversity providing the substrate diversity observed across the different enzyme forms. For example, α -class GSTs show substrate specificity for cumene hydroperoxide (CuOOH) and 7-chloro-4-nitrobenz-2-oxa-1,3-diazole (NBD-C1), due to unique structural component proximal to the H-site, there is a short three-residue β -strand near the C-terminal segment and a longer α -7 helix (due to insertions at the N-terminus and near to the middle of this helix); domain I is formed from two separate segments of the sequence. This occurs because an extra helix (α -11) formed via folding of the C-terminal region of the polypeptide chain is also part of this domain. This helix covers the substrate bound in the H-site, which is thought to explain the preference of α -class GSTs for more hydrophobic compounds. In fact, different GSTs have unique linear free energy plots relative to hydrophobicity in the form of alkyl chain length (Fig. 7.38) [316].

Figure 7.38 Linear free energy relationship between inhibitory potency and hydrophobicity.

Product inhibition and transition state analogs of GST metabolites provide information regarding structure function of GST enzymatic activity. Nucleophilic substitution between GSH and chlorodinitrobenzene leads to formation of Meisenheimer complex (σ -complex) (Fig. 7.37) [317]. The complex presents as a competitive inhibitor of rat isoform 3-3 with a $K_i = 20 \mu\text{M}$. The generation of anionic tripeptide analogs of GSH where the thiol group was replaced with carboxylic acid functional group yielded competitive inhibitors to GSH [313]. Most notably the substitution of the cysteine residue for 2-aminomalonyl derivative yielded a K_i of $0.74 \mu\text{M}$. Chen *et al.* [318] employed the use of GSH in comparison to three GSH analogs in concert with several 4-substituted L-halo-2-nitrobenzenes to investigate the catalytic mechanism of rat liver GSH transferase (isozyme 4-4). The observed substituent effects were consistent with a catalytic mechanism where the Meisenheimer complex formation is rate-limiting or partially rate-limiting step of conjugation (Fig. 7.37). Structural variants of GSH peptides affected the effective pK_a of the thiol and altered the orientation of the thiol toward the nucleophile [318]. The design of novel bivalent inhibitors have been used to realize the in-solution distance of the two H-sites from different dimerized forms of GST [319]. Endogenous ligands have also proven useful as tools to study structure function of GST. S-Nitroso glutathione serves as a carrier for NO and has been demonstrated to be a competitive reversible inhibitor of GSH with a K_i of $180 \mu\text{M}$ [320].

In comparing the structural differences across GST classes, the helix $\alpha 2$ region displays significant variance and not surprisingly comprises part of the H-site. The helix $\alpha 2$ region has been established as a flexible region in the protein that influences catalysis in human GSTP1-1 [321,322]. For instance, S-nitrosoglutathione (GSNO) was shown to modify Cys47 in a temperature dependant fashion. Below physiological temperature, GSNO does not readily label the buried Cys residue, but under physiological conditions, the modification leads to enzyme inactivation. Mobility of the GST has also been identified and characterized by Atkins *et al.* [64].

Single-residue substitutions have also revealed significant information regarding active-site structure activity. Ile104 in GSTP1-1 is a critical residue affecting the binding at the H-site as demonstrated by unique binding of 6-(7-nitro-2,1,3-benzoxadiazol-4-ylthio)hexanol in the wild-type and mutant enzyme [323]. The significance of the histidine residue depicted in the catalytic mechanism of Fig. 7.37 was explored with hGSTM1a-1a and mutagenesis studies to demonstrate the critical role for His107 in catalysis [324]. Numerous other mutagenesis studies have highlighted important active-site residues in G- and H-sites [64,325,326].

7.3.3 Sulfotransferase

The cytosolic sulfotransferases catalyze the conjugation of a sulfate moiety to a nucleophilic acceptor molecule (Fig. 7.39). Sulfotransferases utilize 3'-phosphoadenosine-5'-phosphosulfate (PAPS) as the universal sulfuryl donor to increase the water solubility and decrease the biological activity of the acceptor substrate, though examples of bioactivation do exist [327–330]. Known acceptor moieties for sulfotransferase reactions include phenolic and aliphatic hydroxyl groups as well as N-substituted hydroxylamines [331]. Unprotonated amines can also undergo sulfation, resulting in the formation of a sulfamate product [332].

Figure 7.39 Example of sulfotransferase metabolism reaction with estradiol.

The proposed reaction mechanism for sulfotransferases involves an S_N2 nucleophilic attack on the sulfate moiety of PAPS by the acceptor substrate. As many of these substrates have pK_a values of ~ 6.4 – 9.0 and thus insufficient nucleophilicity at physiological pH, it has been suggested that a conserved histidine residue acts as a catalytic base to deprotonate the acceptor molecule [333], while active-site serine and lysine residues serve to orient PAPS in the sulfotransferase active site (Fig. 7.40) [334]. The overall basicity of the catalytic histidine residue is increased through hydrogen bonding with neighboring threonine residues, which serve to distribute the resulting charge on the histidine. Following the formation of a ternary sulfotransferase-PAPS-deprotonated acceptor molecule complex, a trigonal bi-pyramidal transition state intermediate has been proposed [335]. This transition state geometry may be stabilized by highly conserved serine and lysine residues that interact with the bridging oxygen of the 5'-phosphate group of PAP [333,334,336]. As the lysine residues may also directly catalyze the cleavage of the sulfate moiety from PAPS, an in-line displacement reaction mechanism has been proposed for sulfation. The ordering of the sulfation reaction appears to differ between species and sulfotransferase isoforms, as kinetic studies with rat aryl sulfotransferase suggest either a random bi-bi mechanism or an ordered Theorell–Chance mechanism [337], while a random bi-bi mechanism has been proposed for mouse and human SULT1E1 [338] and multiple studies with additional human sulfotransferases have suggested an ordered bi-bi mechanism in which PAPS binds before the acceptor molecule [339–341]. Interestingly, studies with bacterial sulfotransferases have implicated a random two-site ping-pong bi-bi mechanism, whereby PAPS and the sulfate acceptor molecule bind randomly and independently of each other [342].

Sulfotransferase enzymes can exhibit stereoselectivity among chiral substrates, as is observed with the increased sulfation rate of (*R*)-4'-hydroxypropranolol as compared to (*S*)-4'-hydroxypropranolol [343]. Additional examples include salbutamol, albuterol, isoprenaline, and various hydroxysteroid analogs [343–349]. While active-site characteristics may play a role in the preferred sulfation of one enantiomer over the other, steric interactions within the substrate molecule must also be considered. Studies with

Figure 7.40 Proposed mechanism of SULT-catalyzed sulfation.

chiral aryl alcohols such as 1-(1-naphthyl)ethanol have suggested that spatial orientation may either sterically inhibit the interaction of the PAPS sulfate group with the nucleophilic site on the acceptor molecule or conversely, may orient the nucleophilic site in too distal a position to allow an S_N2 attack to occur on the sulfate group [344]. The resulting conformational rotation needed to overcome the stereoselectivity imposed by the spatial orientation of the substrate molecule would require a significant amount of energy and as such does not readily occur (Fig. 7.41).

From the standpoint of the acceptor molecule, substrate specificity appears to be linked to a number of molecular descriptors, including the size of the acceptor molecule, local structural features, lipophilicity, and electronic characteristics [350–352]. For example, both chain length as well as substituent positions (ortho-, meta-, and para-)

Figure 7.41 Conformational energies of chiral aryl alcohols. *Source:* Reproduced with permission from Banoglu E, Duffel MW. *Chem Res Toxicol* 1999;12(3):278–285.

have been shown to play a role in the substrate profiles of SULT1A1 and SULT1A2 [108,353]. Meanwhile, relationships have been developed between the K_m for a series of phenol sulfotransferase ligands and their respective $\log P$ values, molar refractivities, and Hammett constants [350]. Finally, the presence of a formal charge at physiological pH may also affect the substrate specificity for a given sulfotransferase, as observed for SULT1A3. Tyramine, which contains a primary amine that is positively charged at physiological pH, binds to SULT1A3 with an affinity that is 200-fold greater than that of *p*-ethylphenol, a structurally similar compound to tyramine that differs in only the lack of the primary amine [354].

7.3.4 *N*-Acetyltransferase

Mammalian *N*-acetyltransferases (NATs) are cytosolic proteins that transfer an acetyl group from acetyl coenzyme A to xenobiotics (Fig. 7.42) [355]. Two isozymes are known, NAT1 and NAT2, which differ in tissue localization and substrate selectivity. NAT1 is found in a variety of tissues including liver, colon, blood, and skeletal muscle [356]. NAT2 is present mainly in the liver and gut [357]. The biological function of NATs outside of xenobiotic metabolism is unclear; the only other known role of NATs is involvement in folate catabolism [358].

Figure 7.42 Example of NAT metabolism with dapsone.

Figure 7.43 NAT catalytic cycle.

The general requirement for NAT conjugation is the presence of an aromatic amine. The catalytic cycle of NAT conjugation is complex and proceeds through a ping-pong bi-bi mechanism [355]. The reaction is initiated through acetylation of an active-site cysteine by acetyl-CoA (Fig. 7.43). Activation of the active-site cysteine is aided by adjacent histidine and acidic residues [359,360]. The positioning of the C-terminal region of human NATs may also facilitate interactions with acetyl-CoA, as a serine residue is within hydrogen bonding distance of the adenine ring (N6) of acetyl-CoA [361]. The acetyl group is then transferred from the enzyme to the substrate, forming an acetylated product and releasing the enzyme.

The hydrophobic nature of the active-site pocket may contribute to the stability of the acetylated enzyme intermediate [356]. While the lifetimes of these intermediates is NAT-dependent, the estimated half-life in hamster is 88 s [359]. Variable access of water to the active site, resulting in competing hydrolysis, may explain lifetime differences. Further evidence to support this hypothesis includes kinetic models, which are most consistent with reaction of unionized anilines with the reactive species. Ionized alkylamines, which tend to remain unionized at physiological pH, generally do not react with NATs [356].

NAT1 and NAT2 exhibit different substrate selectivity. Substrates for NAT1 include *p*-aminobenzoic acid and *p*-aminophenol [362]. Substrates for NAT2 include sulfmet-hazine, dapsone, and procainamide [363]. Substrate selectivity may be explained by differences in active-site topography. The active site of NAT1 is ~40% smaller than

NAT2 [364]. The NAT1 active site contains an arginine residue (Arg127) that is available for hydrogen bonding to acidic moieties and a phenylalanine residue (Phe125) that is closely located to orient linear, aromatic substrates toward the acetylated cysteine through π -stacking [365]. In contrast, docking studies based on the NAT2 crystal structure suggest that a phenylalanine residue (Phe93) is positioned to interact with hinged-aromatic substrates such as sulfmethazine [361]. The Phe125Ser mutation conferred NAT1 activity to NAT2 [366].

7.3.5 Acyl-CoA Synthetase

The acyl-CoA synthetases (also referred to as *acyl-CoA ligases*) catalyze the formation of thioester conjugates from carboxylic acids (Fig. 7.44). The activation of endogenous and xenobiotic acids to their thioester conjugates is often the first step in detoxification processes that end in amino acid conjugation and subsequent elimination [367]. The acyl-CoA synthetases are classified by their substrate specificity

Figure 7.44 Example of acyl-CoA synthetase metabolism reaction with *p*-chlorobenzoic acid.

(short chain, medium chain, and long chain) and primary pharmacophores include aromatic carboxylic acids as well as some aliphatic and arylacetic acids [368]. Well-characterized substrates include nonsteroidal anti-inflammatory drugs such as ibuprofen and flunoxaprofen, hypolipidemic drugs such as clofibrate, and the environmental pollutant 4-chlorobenzoate [369–378].

The initial step in the acyl-CoA synthetase catalyzed reaction involves a nucleophilic attack of a carboxylate anion on the α -phosphate group of adenosine triphosphate (ATP) resulting in the formation of an acyl-adenylate intermediate, which does not dissociate from the acyl-CoA synthetase [379]. The acyl-adenylate intermediate then reacts with a deprotonated coenzyme A molecule resulting in the activated thioester conjugate and free adenosine monophosphate [380]. It has been proposed that the acetyl-CoA synthetase may adopt a different conformation for each step in the reaction [381]. The esterification of the carboxylate moiety has been proposed to proceed via a unidirectional bi-uni-uni-bi ping-pong mechanism [382]. Proper orientation of the reactants in the active site of acyl-CoA synthetase is achieved through hydrogen bonding with active-site residues as well as through coordination with a divalent magnesium ion [378,381–383].

A unique attribute of acyl-CoA synthetases is their involvement in the chiral inversion of nonsteroidal anti-inflammatory drugs such as ibuprofen, flunoxaprofen, and 2-phenylpropionic acid [373,375,377,384], resulting in a unidirectional inversion of the (*R*)-enantiomer to the (*S*)-enantiomer. In each case, the acyl-CoA enzyme displays a stereoselective preference for the formation of a thioester conjugate of the (*R*)-enantiomer, with a minimal amount of acyl-CoA transfer to the (*S*)-enantiomer. Using ibuprofen as an example, the first step in the chiral inversion process is the formation of an (*R*)-ibuprofen-CoA thioester intermediate (Fig. 7.45), as demonstrated through studies utilizing deuterium-labeled ibuprofen [385]. The next step involves the abstraction of the C2 proton of the ibuprofen-CoA conjugate by epimerase/carnitine dehydratase. Though the inherent acidity of this proton is increased by the presence of the thioester conjugate, the deprotonation step is not spontaneous at physiological pH and requires the presence of a catalytic base provided by epimerase [372,375,386]. The resulting carbanion tautomerizes to the planar and more stable enolate, allowing for a proton attack from either side of the double bond to form both enantiomers of the ibuprofen thioester conjugate. Finally, hydrolysis of the thioester bond by acyl-CoA hydrolase results in the formation of unconjugated (*S*)-ibuprofen [375,377,387].

While substrate specificities may vary among the different acyl-CoA synthetase homologs, the enzymes generally catalyze the thioester conjugation of aliphatic and aromatic carboxylic acids. For the aliphatic acids, the acyl chain length is often the determining factor in the specificity of individual acyl-CoA isoforms. In addition, both the pK_a of the carboxylic acid as well as the $\log P$ of the compound have been shown to be important determinants in the formation of thioester conjugates [368,388,389], though electronic and steric factors may also play a role. For example, examination of the rates of thioester formation for a series of cinnamic acid analogs with various electron-donating or electron-withdrawing groups in the para-position resulted in a biphasic Hammett plot (Fig. 7.46), implicating the importance of a negative charge in formation of the conjugate as well as a potential change in the rate-determining step in the reaction for electron-donating versus withdrawing groups [390]. Sterically, compounds with a flat hydrophobic region that is coplanar to the carboxylic acid moiety appear to be much better substrates for acyl-CoA synthetases [391]. It has been

Figure 7.45 Proposed acyl-CoA synthetase reaction mechanism resulting in stereoinversion of (*R*)-ibuprofen to (*S*)-ibuprofen.

suggested that compounds that do not meet this coplanar criteria may have difficulty accessing the active site of the enzyme.

7.3.6 Methyltransferase

The methyltransferase family of enzymes (including thiopurine-*S*-methyl transferase, thiol methyltransferase, catechol-*O*-methyltransferase, phenethanolamine-*N*-methyltransferase, and multiple other forms involved in biological homeostasis) catalyze the transfer of a methyl group from *S*-adenosyl methionine to nucleophilic substrate [392–394]. Drugs that are metabolized by methyltransferases include 6-mercaptopurine, 6-thioguanine, and azathioprine (thiopurine-*S*-methyl

Figure 7.46 A Hammett plot for acyl-CoA synthetase reactions with para-substituted cinnamic acids. *Source:* Reproduced with permission from Koetsier MJ, *et al. Biochem J* 2009;417:467–476. © The Biochemical Society, <http://www.biochemj.org>.

transferase), dopamine, L-3,4-dihydroxyphenylalanine and isoprenaline (catechol-*O*-methyltransferase), captopril and D-penicillamine (thiol methyltransferase), and norepinephrine (phenethanolamine-*N*-methyltransferase) [395–404].

The mechanism by which methyltransferases catalyze the addition of a methyl group to a substrate proceeds via an S_N2 nucleophilic attack on the methyl carbon of *S*-adenosyl methionine by the substrate (Fig. 7.47). The reaction may require the presence of Mg^{2+} (catechol-*O*-methyltransferase) and has strict geometrical requirements for the orientation of substrate and cofactor [396,405,406]. An ordered mechanism has been suggested for the transfer of the methyl group, with the order of binding

Figure 7.47 Example of methyltransferase metabolism reaction with norepinephrine.

Figure 7.48 Proposed methyltransferase reaction mechanism.

being (i) *S*-adenosyl methionine; (ii) Mg^{2+} ; and (iii) substrate [407–409]. Following transfer of the methyl group, *S*-adenosyl homocysteine (the demethylated byproduct of *S*-adenosyl methionine) is the last ligand to dissociate from the binding pocket of the methyltransferase [410,411]. Kinetic isotope effect studies and hybrid density functional theory models have been used to identify the transfer of the methyl group as the rate-limiting step in the reaction [393,412,413]. In a similar manner to other enzyme-catalyzed S_N2 reactions (i.e., glucuronidation and sulfation), a conserved active-site lysine residue (catechol-*O*-methyltransferase) or arginine residue (thiopurine-*S*-methyltransferase) acts as a catalytic base to deprotonate the nucleophile before the S_N2 attack (Fig. 7.48) [398,414].

Substrate selectivity varies widely across the range of methyltransferases. For catechol-*O*-methyltransferases, which catalyze the transfer of a methyl group to catechols and catecholestrogens, it appears that the presence of vicinal aromatic hydroxyl groups is a requirement for catalysis, as the enzyme does not bind the nonaromatic dihydroxyl cyclohexane analogs [415,416]. In addition, the presence of a strong electron-withdrawing group on the catechol has been shown to greatly decrease the rate of *O*-methylation, though the compounds can still bind and inhibit the enzyme [417–419]. Orientation of the substrate within the active site is controlled by the bound magnesium ion, which is coordinated to active-site aspartate and asparagine residues, a bound water molecule, and both hydroxyl groups of the catechol, while overall substrate selectivity may be conferred by hydrophobic “gatekeeper” residues (Fig. 7.48). For thiol methyltransferases, the preferred substrates are aliphatic sulfhydryl-containing compounds, such as 2-mercaptoethanol [420]. Potent inhibitors of thiol methyltransferase include the calcium channel blocker SKF 525A [421]. Lastly, while thiopurine methyltransferases catalyze the methylation of

thiopurines, thiopyrimidines and aromatic sulfhydryl compounds, a natural substrate has not yet been identified [402,414,422]. Though compounds with a purine moiety are understandably the primary substrates for thiopurine methyltransferase, the presence of a heterocyclic aromatic functional group is not a requirement for substrate recognition, as demonstrated by studies with thiophenol-containing compounds [402,423]. Substrate recognition by thiopurine methyltransferases also appears to be dependent on the ability of the acceptor molecule to achieve proper orientation within the substrate-binding site of thiopurine methyltransferase through hydrophobic and van der Waals interactions [414].

Methyltransferases are also known to display both stereoselectivity and regioselectivity in the transfer of a methyl group to an acceptor molecule. Regioselectivity by methyltransferases has been observed for the methylation of catechols by catechol-O-methyltransferase, with 3-O-methylation (meta) generally preferred over 4-O-methylation (para), especially *in vivo* [398,407]. Furthermore, dimethylation is not readily observed. This observed phenomenon may be due in part to the unfavorable interactions required between the substrate and hydrophobic active-site residues to allow the 4-hydroxy position to gain proper alignment for an S_N2 attack on *S*-adenosyl methionine. The catechol-O-methyltransferases also exhibit stereoselectivity in the methylation reaction, as noted with a series of β -adrenoceptor agents, where the enzyme preferentially catalyzed the methylation of (–)-isoprenaline and (–)-noradrenaline over their respective (+) counterparts [424].

7.4 CONCLUSION

Understanding the biochemistry of drug metabolism is one of the most critical aspects of new drug development to assure safe and efficacious medicines of the future. As described in this chapter, drug metabolism is heavily dependent on the molecular properties of the substrate and the topography of the enzyme's active site. Considerable advances have been made in recent years, such that basic rules can be applied to determine the fate of a compound in man based on physicochemistry character and structure of a drug metabolite. In this light, the impact of the identification of drug metabolites allows the drug metabolism scientist to predict drug clearance pathways and factors affecting drug/metabolite exposures early in the drug development process. Moreover, it is anticipated that a strong understanding of the chemical basis for metabolite formation will greatly enhance our ability to elucidate the mechanisms involved in idiosyncratic drug reactions and off-target toxicity.

In addition to gaining greater insights into the biochemical factors that influence the chemistry of drug metabolism, other technological and analytical advances will continue to be made and their application will continue to grow, which should enable scientists to have even greater impact in the area of drug metabolism. Of course, in order to have the greatest benefits from these advances, drug metabolism scientists need to embrace and incorporate emerging trends in science and technology, select the appropriate tools, and accurately interpret data generated from drug metabolism studies with a link toward the fundamental chemistry associated with the observed biotransformation. We hope the present work provides a reasonable chemical foundation for the biochemistry of drug metabolism on which both experienced and newly initiated drug metabolism scientists may rely on.

8.1 SUMMARY

Drug-metabolizing enzymes (DMEs) are primarily expressed in the liver but their role in the extrahepatic tissues such as gastrointestinal tract (GIT), pulmonary, excretory, nervous, cardiovascular system, and skin cannot be neglected. Generally, the expression of DMEs in extrahepatic tissues is quantitatively lower than that in the liver, but there are a few enzymes such as CYP1A1, CYP1B1, CYP2F1, and CYP2U1 that are more abundant in extrahepatic organs. As many extrahepatic organs are portals for administered drugs, DMEs expressed in these organs can be responsible for significant metabolism, leading to first-pass effects and lower bioavailability. Extrahepatic DMEs are also involved in bioactivation of prodrugs and formation of reactive metabolites that may interact with cellular components, resulting in organ-specific toxicity. Activity and expression of extrahepatic DMEs is often altered by coadministered drugs, leading to drug–drug interactions. Expression of DMEs in living beings affected by a host of

environmental and genetic factors such as genetic polymorphism, age, gender, pathophysiological conditions, inborn errors in metabolism, food habits, and environmental pollutants, contributing to varied drug effects and idiosyncratic toxicities.

8.2 INTRODUCTION

There was a stage when it was believed that DMEs in the liver were mainly responsible for the protection of the body against exogenous challenges (environment, diet, drugs, chemicals, etc.), while adrenal glands were involved in the metabolism of endogenous steroids. With time, DMEs have been found in extrahepatic organs and tissues including GIT, pulmonary, urinary, central nervous system (CNS), and cardiovascular system (CVS), as well as in skin, placenta, adrenal glands, reproductive organs, plasma, eyes, pancreas, and mammary glands. However, overall quantitative expression of extrahepatic DMEs represents just 10–20% of total hepatic metabolism. Nevertheless, some DMEs are found expressed solely in extrahepatic organs and tissues. Extensive studies have shown that extrahepatic enzymes play a significant role in drug metabolism and detoxification of environmental/food contaminants and provide protection to specific organs and the body as a whole.

A number of factors such as genetic makeup, age, gender, pathophysiological conditions, and environmental factors contribute to differential expression of DMEs in extrahepatic organs. The expression of DMEs, especially of cytochrome P450s (CYPs), is greatly influenced by both age and gender, and varies from fetal to geriatric age because of environmental factors as well as changes in levels of sex hormones. These DMEs contribute to bioactivation and deactivation of xenobiotics and to the development of diseases, especially cancer. The Human Genome Project has identified a correlation between extrahepatic CYPs and development of both solid and hematological malignancies.

DMEs in the GIT influence bioavailability of drugs significantly and drug clearance is dependent upon the rates of metabolism from hepatic and extrahepatic organs, in addition to the rate of excretion of the unchanged drug. These changes in turn affect the efficacy and safety of drugs by influencing their concentration and that of their metabolite(s) at the site(s) of action, which can result in severe drug–drug interactions in case of polypharmacy.

This chapter provides a comprehensive review of the type and nature of DMEs expressed in organs and tissues of the body, excluding liver. It also encompasses factors affecting the expression of extrahepatic DMEs, such as genetic polymorphism, age, gender, pathophysiological conditions, and food habits. Additionally discussed are observations on bioactivation and deactivation of xenobiotics, bioavailability and toxicity of drugs, and drug–drug interactions.

8.3 DISTRIBUTION AND EXPRESSION OF DMEs IN EXTRAHEPATIC TISSUES

Liver is quantitatively and qualitatively the most important site for metabolism of xenobiotics, including therapeutic drugs that enter the body after absorption from the GIT. A majority of the DMEs are expressed in the liver, although not evenly distributed

in the organ. DMEs such as CYPs are highly concentrated in the periportal region of the liver, while other enzymes such as glutathione *S*-transferases (GST) are expressed in the centrilobular of liver. This uneven distribution provides significant protection to this vital organ, for example, if toxic electrophilic intermediates are generated then only pericentral necrosis will occur, rather than massive necrosis [1].

DMEs similar to those expressed in the liver are also expressed in the extrahepatic organs. The distribution of DMEs in extrahepatic organs and tissues is depicted in Fig. 8.1 and detailed information, based on current literature, is described in Table 8.1. The expression of extrahepatic DMEs varies from organ to organ, depending on exposure to endogenous substances, routinely used drugs and the challenges faced because of food habits and the consequence of exposure to environmental contaminants [2–5]. There are some instances where DMEs show higher expression in extrahepatic tissues relative to the liver because of exposure to certain environmental components or because of life style choices (e.g., smoking or type of food intake).

8.3.1 CYPs and Subtypes

CYPs are monooxygenases and consist of an apoprotein and a heme moiety that is common to all isoforms. CYPs are involved in reactions that include hydroxylation, sulfoxidation, epoxidation, deamination, desulfuration, dehalogenation, peroxidation, *N*-oxide reduction, *N*-dealkylation, *O*-dealkylation, and *S*-dealkylation. CYPs constitute the largest family of DMEs localized in every organ of the body and are categorized based on amino acid sequence similarities. Among CYPs, CYP1, CYP2, and CYP3 are the major types responsible for the metabolism of xenobiotics [125]. The distribution of CYPs varies across the body. Pie charts depicting relative distribution of CYPs in different human organs are shown in Fig. 8.2 [126]. The total specific contents of CYPs in small intestine, lungs, kidneys, and brain have been observed to be 0.02–0.21 [127], ~0.01 [128], 0.1–0.2 [129], and ~0.1 nmol/mg [15], respectively.

8.3.1.1 Gastrointestinal Tract. Orally administered drugs first come in contact with CYPs located in epithelial cells of GIT. Major activity of CYPs at the cellular

Figure 8.1 Distribution of drug-metabolizing enzymes in extrahepatic organs and tissues in humans.

TABLE 8.1 Location of Drug-Metabolizing Enzymes in Extrahepatic Organs and Tissues

Enzyme	Gastrointestinal Tract	Pulmonary System	Urinary System	Central Nervous System	CVS	Skin
CYP1A1	Enterocytes, esophagus 6	Bronchial epithelial cells, capillary endothelium, alveolar epithelium, alveolar type I and II cells, ciliated columnar epithelial cell lining, bronchoalveolar airways, alveolar macrophages 7	PCT 8	Cerebellum, cortex, basal ganglion, hippocampus, substantia nigra, pons, medulla oblongata 9,10	Left and right ventricles 11,12, coronary smooth muscle cells 13	Epidermis 14

Figure 8.2 Percentage of expression of CYP mRNA in different organs. *Source:* The figure is based on data from Nishimura *et al.* [126].

level is in the villous tips and decreases in the direction of crypts. At the tissue level, CYP activity gradually decreases from the duodenum to the colon [127]. CYP1A1, CYP2C9, CYP2C19, CYP2D6, CYP2J2, CYP3A4, and CYP3A5 are the primary enzymes expressed in the GIT. In addition, CYP1A2, CYP2A6, CYP2A13, CYP2E1, CYP2F1, CYP2B6, and CYP2S1 are expressed at lower levels. Recently, mRNAs for CYP2S1, CYP2R1, CYP2U1, and CYP2W1 have been reported in the GIT but their contribution to the drug metabolism is not yet known [33,127].

The specific content of CYP1A1 in the small intestine varies from 3.6 to 7.7 pmol/mg of protein [127]. CYP1A1 expression is regulated by aryl hydrocarbon receptor (AhR) [130]. The ligands for the receptor are aromatic hydrocarbons, which are toxic to the body [131]. Zhang *et al.* correlated the expression of AhR with CYP1A1 along the length of the intestine from duodenum to ileum and found expression diminished markedly along the oral direction of intestine [130,132]. The extent of induction of CYP1A1 expression and activity could be related to the challenges faced, for example, exposure to polyaromatic hydrocarbons (PAHs) [24]. This enzyme can be induced in GIT by smoking, omeprazole, β -naphthoflavone (BNF), 3-methylcholanthrene, isosafrole, cyclohexanol, albendazole, phenobarbital, imazalil (food contaminant), benzo(α) pyrene, green tea extract and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) [133–139]. Although like CYP1A1, CYP1B1 is also regulated by AhR, no expression of this enzyme has been detected in the intestine [24].

Expression of CYP2B1/2 is reported to be 137 pmol/mg microsomal protein in the upper villi and it is not detected in the crypt cells of the human intestine except in the induced state, for example, by phenobarbital and imazalil [135,140]. CYP2B6 mRNA has also been reported in the human intestine, although its activity is not established [141].

CYP2C9 constitutes 15% of the total CYP content, with an average specific content of ~ 8 pmol/mg, as compared to 89 pmol/mg microsomal protein in the human liver [142]. The presence of this enzyme in the intestine is responsible for poor bioavailability of fluvastatin [127]. CYP2C19 constitutes 2% of the total CYP content in the human intestine, with a specific content of 2 pmol/mg microsomal protein [142]. mRNA expression of CYP2C isoforms in the human intestine is in the order of CYP2C9 = CYP2C18 > CYP2C19 > CYP2C8, while protein expression is in the order of CYP2C9 > CYP2C19 > CYP2C8 (below limit of quantification) > CYP2C18 (not detected) [143]. In human jejunum, both CYP2C9 and CYP2C19 exhibit polymorphisms [26] with a 19-fold interindividual variation in CYP2C19 activity [143].

The expression of CYP2D6 in the human intestine is reported to be 0.9 pmol/mg microsomal protein, which is ~ 14 times lower than the liver. Its concentration decreases in the order of jejunum > duodenum > ileum [144]. Although CYP2D6 shows 100-fold interindividual content variation in the intestine, while clinically, its contribution to first-pass metabolism is not significant [144]. CYP2E1 mRNA is detected in the intestine, but its activity has not been established [127]. CYP2J2 (arachidonic acid epoxygenase) constitutes about 1.4% of the total human intestinal CYPs [142], with a specific content of 2.1 ± 0.6 pmol/mg protein [145]. Its protein expression is relatively constant across the GIT [30]. CYP2J2 contributes to the first-pass metabolism of nonsedative antihistamines, astemizole, and ebastine [145]. CYP2S1 is highly expressed in epithelial cells of the GIT, with its expression being higher in the basal cell layer of the stratified squamous epithelium of esophagus. In stomach, CYP2S1 is located in the mucus secreting epithelial cells of the glandular mucosa covering the fundus and body. Its expression in the duodenum is strong in the columnar epithelial lining of the villi, in crypts, as well as in the cells surrounding the glands in the lamina propria. It is also located in the glandular epithelium of both colon and rectum [34].

CYP3A is the major enzyme expressed in the gut and constitutes up to 82% of the total CYPs [142]. CYP3A4 expression is highest in the small intestine and lowest in the stomach [146]. The specific content of CYP3A4 protein in human duodenum, distal jejunum, and distal ileum is in the range of 3–90, 2–98, and 2–38 pmol/mg, respectively [147]. CYP3A4 expression is regulated by the pregnane X nuclear receptor (PXR) [148] and induced by drugs such as rifampicin [149], phenobarbital [150], sodium arsenite [151], nafcillin, and dicloxacillin [152]. Intestinal CYP3A can also be inhibited by drugs including maslinic acid, corosolic acid, ursolic acid [153], ketoconazole [154], and imazalil [155]. CYP3A inhibitors and inducers affect the bioavailability of orally administered CYP3A substrates.

8.3.1.2 Pulmonary System. DMEs in the pulmonary system are responsible for the metabolism of drugs and also of environmental pollutants such as organic solvents and PAHs that are present in inhaled air [156]. Despite relatively low expression, these enzymes provide protection to the brain from inhaled chemicals and are important for homeostasis and metabolism of odorant molecules [157]. Apart from inhaled xenobiotics, drugs given by parenteral routes have the potential to accumulate in the lungs

as 100% of the cardiac output reaches the pulmonary system before passing through the liver and undergoes metabolism. Examples include amiodarone, imipramine, lidocaine, propranolol, pethidine, amphetamine, chlorphentermine, chlorpromazine, local anesthetics, and fentanyl [158–160].

The CYPs expressed in the pulmonary system are CYP1A1, CYP1A2, CYP1B1, CYP2A6, CYP2A13, CYP2B6, CYP2C8, CYP2C18, CYP2D6, CYP2E1, CYP2F1, CYP2J2, CYP2S1, CYP3A4, CYP3A5, CYP3A43, and so on [7,156]. Of these CYP1A1, CYP1B1, CYP2A13, CYP2E1, CYP2F1, CYP2S1, and CYP3A5 are abundantly expressed in the pulmonary system at concentrations higher than that in the liver [7].

CYP1A1 is inductively expressed in bronchial epithelial cells, capillary endothelium, and alveolar epithelium of the human lungs in response to inhaled chemicals such as TCDD, BNF, pyridine, acetone, benzo(α)pyrene (cigarette smoke constituent), 3-methylcholanthrene, TCDD, nicotine, omeprazole, 2-hydroxypyridine, 7,12-dimethylbenzo(α)anthracene, and diesel exhaust [7,161–166]. Its presence in the epithelium of bronchi is restricted to airways with a diameter greater than 1 mm [7]. A study to estimate the influence of smoking on the expression of CYP1A1 revealed that specific content of this isoform in nonsmokers was 6.0 pmol/mg in comparison to $\sim$ 15.5 and 19.0 pmol/mg in smokers and ex-smokers, respectively [167]. In contrast to CYP1A1, CYP1A2 is expressed constitutively [132], although inhaled benzo(α)pyrene and diesel exhaust can lead to its induction [166].

CYP1B1 is expressed in alveolar type I and II, ciliated columnar epithelial, alveolar macrophage epithelial, and bronchial epithelial cells of the human lungs [7,167]. It is responsible for 2- and 4-hydroxylation of 17-estradiol and metabolic activation of PAHs and aromatic amines, similar to CYP1A1 [166]. CYP1B1 has five-fold higher expression in the smokers' lungs [167]. Its expression is reported to be 1.8, 1.0, and 4.4 pmol/mg microsomal protein in smokers, nonsmokers, and ex-smokers, respectively [167].

In the human lungs, CYP2A6 and CYP2A7 are present in the trachea and alveolar epithelium, respectively [7]. CYP2A6 is prominently expressed in the liver and also found in the pulmonary system with mRNA expression of 9 ± 1 , 76, and 160 ± 140 amol/mg RNA in lungs, trachea, and nasal mucosa, respectively [20]. CYP2A7 is virtually quiescent or absent in the human nasal mucosa and lungs [168]. CYP2A13 is present in pulmonary epithelial cells and the bronchial mucosa, with highest expression in the nasal mucosa, while hepatic expression is below the limit of quantitation [7]. mRNA expression in the lungs, trachea, and nasal mucosa is 78 ± 32 , 130, and 750 ± 210 amol/mg RNA, respectively. The specific content of CYP2A13 in microsomes is in the range of 0.26–0.56 nmol/mg proteins [20]. It is associated with metabolism of 2'-methoxyacetophenone, 2,6-dichlorobenzonitrile, hexamethylphosphoramide (HMPA), *N,N*-dimethylaniline, *N*-nitrosodiethylamine (NDEA), *N*-nitrosomethylphenylamine, aflatoxin B, and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NKK) [7]. CYP2B6/7 isoforms are located in bronchial epithelial cells and alveolar type II pneumocytes. CYP2B6 is associated with oxidation of NKK in the human lungs and bioactivation of the prodrug, cyclophosphamide [7].

CYP2C8 and CYP2C18 are predominantly expressed in serous cells of bronchial glands, bronchial mucosa, and peripheral tissues of the human lungs, while CYP2C9 shows very low expression in the bronchial mucosa [7,27]. CYP2C8 is believed to have a role in regulation of the pulmonary vascular and bronchial tone [159]. This

subfamily is involved in metabolic activation of drugs as well as carcinogens [27]. CYP2C18 has more abundance in the trachea, as compared to CYP2C19, which is predominant in the human lungs [27].

Guidice *et al.* [169] examined gene expression of CYP2D6 in the human bronchial mucosa and lung parenchyma and reported that the mean levels of CYP2D6 mRNA in the bronchial mucosa and lung parenchyma were three- and six-folds, respectively, lower than the liver and that the gene was nonuniformly distributed within the lung. CYP2E1 is present in the bronchial, bronchiolar and alveolar epithelium, endothelial cells, and the nasopharynx, and reported to metabolize tobacco-specific nitrosamines, such as *N*-nitrosodimethylamine (NDMA), *N*-nitrosodibutylamine, and *N*-nitrosodiethylamine [159,170]. CYP2E1 expression is significantly higher in lung adenocarcinomas and is induced by acetone and ethanol [162]. CYP2F1 is specifically expressed in the human lungs with no or minimal expression in hepatic and other organs [171]. It is responsible for the metabolism of environmental toxicants, such as components of cigarette smoke, gasoline, and industrial by-products such as benzene, styrene, naphthalene, and 3-methylindole [172,173].

The CYP2J subfamily is expressed in bronchial and vascular smooth muscle cells as well as endothelium. The enzymes are involved in epoxidation of arachidonic acid (AA), leading to epoxide AA metabolite, which modulates bronchial smooth muscle tone and airway transepithelial ion transport [7,159,174]. CYP2J2 and CYP2J3 subtypes are primarily expressed in ciliated epithelial cells lining of the airway [174]. CYP2S1 is expressed in the upper and lower respiratory systems, in particular, in the nasal mucosal epithelium of the upper respiratory tract, and at high levels in the epithelium of bronchus and cuboidal and columnar epithelia of bronchioles in the lung. The enzyme is induced by TCDD and smoking [34,175].

CYP3A is expressed in bronchial epithelium, bronchial glands, alveolar epithelium, vascular epithelium, capillary epithelium, and alveolar macrophages of the human lungs. It is also expressed in the nasal cavity, pharynx, larynx, and trachea [39]. CYP3A4 and CYP3A5 are expressed at a significant level in human lungs, whereas CYP3A7 and CYP3A43 have low expression [39,176]. CYP3A4 is located in epithelium cells of bronchial glands, bronchiolar ciliated and terminal cuboidal, epithelial cells, and type II alveolar epithelial cells [176]. CYP3A5 is present in bronchial and alveolar epithelial cells, bronchial glands, and alveolar macrophages [39]. Its levels are decreased in alveolar macrophages on cigarette smoking [177].

8.3.1.3 Urinary System. CYPs expressed in the human kidneys are CYP1A1, CYP2D6, CYP2E1, CYP2J2, CYP2R1, CYP3A4, CYP3A5, and so on [8,129]. These enzymes are present throughout the kidney, with highest concentrations in the microsomal fraction of the cortex and proximal convoluted tubule (PCT). The specific content of CYP1A1 is <0.005 pmol/mg proteins in each kidney [8]. CYP2E1 is located in the PCT and is induced by pyridine, ethanol, acetone, and pyrazole [129]. It is responsible for nephrotoxicity, as it generates reactive metabolites of chloroform, ipomeanol, 1,1-dichloroethene, and paracetamol [129]. CYP2J2 plays an important role in carcinogenesis and is located in PCT, collecting duct (CD), and distal convoluted tubule (DCT) cells, while it is absent in glomerulus and thin loop of Henle [31]. CYP2S1 is highly expressed in urothelial cell of the urinary bladder and in PCT and DCT of the kidney [34]. CYP3A4 is predominantly expressed in PCT, along with CYP3A5 [129,178].

8.3.1.4 Central Nervous System. The CYPs in the brain are distributed unevenly in different cells and regions. For example, CYP content in mitochondrial fraction of the brain cells is nine times higher than that in the microsomal fraction [179]. CYPs play a diverse role in the brain, including metabolism of xenobiotics, aromatization of androgens to estrogens, formation of catechols, and metabolism of neurotransmitters [180]. Centrally acting drugs, such as analgesics, antidementia agents, beta-blockers, tricyclic antidepressants, antipsychotics, monoamine oxidase inhibitors, and vasodilators, are metabolized in the brain [15]. CYPs are also present in the microvessels and choroid plexus of the brain, which indicates that regulation of the penetration of xenobiotics in the brain compartment might be due to their metabolism in endothelial cells of the blood–brain barrier [180].

The CYPs expressed in the human brain include CYP1A1, CYP1A2, CYP1B1, CYP2B6, CYP2C8, CYP2D6, CYP2E1, CYP2U1, CYP3A4, CYP3A5, and CYP3A43 [15]. The subtypes, CYP1A1, CYP1A2, CYP2B6, CYP2D6, and CYP2E1, are expressed in the cortex, cerebellum, basal ganglia, hippocampus, substantia nigra, medulla oblongata, and pons. Of these, CYP1A1, CYP1A2, and CYP2E1 along with CYP2A6 are expressed in the mitochondria of the striatum, thalamus, pons, and medulla oblongata. CYP1A1 bioactivates PAHs that form adducts with DNA and thus it has the potential to induce carcinogenesis [15]. Interestingly, the structure of human brain CYP1A1 is different than that present in the liver [9]. The CYP2A6 isozyme is mainly responsible for the metabolism of nicotine to cotinine through C-oxidation and also to *trans*-3'-hydroxycotinine by 3'-hydroxylation [181,182]. Some studies have shown that its activity is inhibited by neurotransmitters and steroids, such as tryptamine, serotonin, dopamine, histamine, noradrenaline, adrenaline, estrogen, androgen, and corticosterone [183]. CYP1B1 is predominantly located in the putamen, spinal cord, medulla oblongata, frontal, and temporal cortex and to a lesser extent in cerebellum, hippocampus, thalamus, and amygdale. It is predominantly expressed in the nuclei of a majority of astrocytes and neurons in human brain cortex [15].

CYP2B6 is located in the caudate nucleus, putamen, hippocampus, cerebellum, brain stem, thalamus, and frontal cortex [15]. Induction of CYP2B6 isoform has been reported in monkeys after chronic treatment with phenobarbital [184]. CYP2B6 and CYP2C19 are the major enzymes responsible for metabolism of selegiline, a drug used in the treatment of Parkinson's disease [185,186]. The activity of CYP2B6 toward metabolism of nicotine is reported to be relatively higher than CYP2A6 [15].

CYP2C8 is located in the frontal cortex, putamen, and hippocampus of the brain [187]. Typical CYP2C8 substrates are tricyclic antidepressants, diazepam, and verapamil [15]. CYP2D6 is highly expressed in the cerebral cortex, purkinje and granule cell layers of cerebellum, reticular neurons of midbrain, and pyramidal neurons and its expression in brain fractions, viz putamen, globus pallidus, and substantia nigra, is higher in alcoholics than in nonalcoholics [188–190]. The isoform is involved in metabolism of neurotransmitters, tryptamine, and tyramine [15]. CYP2E1 plays a significant role in fetal alcohol syndrome, as it is induced by ethanol. Increased expression of this subtype was observed in human neuroblast cultured cells treated with nicotine [191]. CYP2S1 is expressed in the white matter of the brain [34]. CYP2U1 is specific to the cerebellum [15] and is involved in the metabolism of arachidonic acid, docosahexaenoic acid (DHA), and other long-chain fatty acids [36].

CYP3A is present in the cortex and basal ganglia where it metabolizes psychoactive drugs, such as codeine [192,193]. The subtypes CYP3A4 and CYP3A43 are expressed

in equal amounts in the brain. CYP3A43 is highly expressed in the brain as compared to the liver and is involved in metabolism of drugs such as alprazolam [194]. CYP3A5 mRNA is reported in the midbrain, basal ganglia, and frontal cortex [42].

8.3.1.5 Cardiovascular System. CYPs play a vital role in modulation of cardiac Ca^{+} current and cell contraction and in maintaining vascular tone by generating epoxides such as 5,6-epoxyeicosatrienoic acids (EETs), 8,9-EETs, 11,12-EETs, and 14,15-EETs from AA [195]. The CYPs expressed in the human heart are CYP1A1, CYP1A2, CYP1B1, CYP2A6, CYP2A7, CYP2C8, CYP2D6, CYP2E1, CYP2J2, CYP2R1, CYP2S1, CYP2U1, and CYP3A4 [196,197]. Of these, CYP1B1 and CYP2J2 are prominently expressed, while CYP1A1, CYP1A2, CYP2B6, CYP2B7, and CYP2C9 are induced [198]. Cardiomyocytes are efficiently involved in metabolism and clearance of drugs from the heart [199].

Healthy human heart shows no expression of CYP1A2, while there is limited expression of CYP1A1 in the left ventricle. In diseased conditions, like dilated cardiomyopathy, CYP1A1 is also detected in the right ventricle, ascending aorta, pulmonary aorta, and right atrium of the heart. CYP1A1 and CYP1B1 are expressed in coronary artery smooth muscle cells and are involved in the conversion of estradiol to hydroxyestradiol, which has cardiovascular protective effects [13].

CYP2C8, CYP2C9, and CYP2J2 show epoxigenase activity in the heart. CYP2C8 and CYP2C9 are present in the right and left ventricle cardiomyocytes [11,12,199] and are induced during ischemic heart injury [198]. CYP2J2 is abundantly expressed in coronary artery endothelial cells, smooth muscle cells, and cardiac myocytes of the normal human heart [200]. Expression of CYP2J2 is aggrandized on exposure with cocaine [201]. CYP2D6 shows very low expression in heart and is involved in the metabolism of verapamil [198]. CYP2E1 is expressed in the endothelium of the endocardium and coronary vessels [16], while CYP2S1 is absent in the heart [34,202]. CYP3A4 is expressed in the endothelium of the endocardium and coronary vessels. The CYP3A4-NADPH-CYP reductase system is involved in formation of nitric oxide from isosorbide dinitrate [16].

8.3.1.6 Skin. CYPs are present in keratinocytes, monocytes, lymphocytes, and fibroblasts of the human skin. CYPs are relatively highly expressed in keratinocytes [203] and also found within the differentiated cells of hair follicles and sebaceous glands, as well as in epidermis [204]. The role of CYPs is to provide protection to exposed skin from ingredients in cosmetics, toiletries, and healthcare products, as well as from many allergens, environment toxicants, and carcinogens. CYP isoforms expressed in human skin are CYP1A1, CYP1A2, CYP1B1, CYP2A6, CYP2C9, CYP2C18, CYP2C19, CYP2D6, CYP2E1, CYP2J2, CYP2S1, CYP2U1, CYP2W1, CYP3A4, and CYP3A5. Among these, CYP2C9, CYP2C18, CYP2C19, CYP2W1, CYP3A4, and CYP4B1 are upregulated by cellular differentiation [17]. CYP1A1 and CYP1B1 are expressed in the differentiated keratinocytes [14] and CYP2U1 is expressed at highest levels in undifferentiated keratinocytes [17].

CYP1A1 is expressed inductively in the human skin and hair follicles [205] and can be induced by ultraviolet (UV) irradiation, PAHs, BNF, polyhalogenated dibenzo-*p*-dioxins, polyhalogenated dibenzofurans and coplanar polyhalogenated biphenyls [14,17,206]. It is involved in the metabolism of benzo(α)pyrene, 3-methylcholanthrene, and 7,12-dimethylbenz(α)anthracene in the skin [203]. CYP1A2 is expressed at mRNA

level in epidermis of the human skin [17]. CYP1B1 is also expressed in the hair follicles and plays a major role in the metabolism of PAHs (7,12-dimethylbenz(α)anthracene). It is induced in the skin on exposure to UV radiation, especially in keratinocytes, basal cell layer, and dermis [14,207].

CYP2A7 mRNA is detected in human skin fibroblasts, although no catalytic activity has been observed [208]. CYP2B6 is reported in foreskin epidermis, epidermis, sebaceous glands, and hair follicles of adult skin [23]. Weak CYP2C mRNA expression is shown in epidermal keratinocytes and dermal fibroblasts of the human skin. This subfamily may play a role in the pathogenesis of drug-induced skin allergy, as this group of enzymes is known to metabolically activate drugs, including phenytoin [209]. CYP2C9 and CYP2C19 are unregulated in epidermal keratinocytes during cellular differentiation, and CYP2C18 is present in the human skin [17,25]. CYP2D6 is detected in dermal fibroblasts, while CYP2E1 is present in the suprabasal cell layers of human foreskin epidermis and keratinocytes [17]. The latter is induced by ethanol, dexamethasone, and salicylic acid [210]. CYP2J, CYP2W, and CYP2R mRNA has been detected in human keratinocytes [17]. CYP2S1 is constitutively expressed in the human skin and can be induced on UV exposure or topical drug treatment. Other factors responsible for CYP2S1 expression in the cutaneous tissue are PUVA (psoralen + UV-A treatment for eczema, psoriasis, graft-versus-host disease, and vitiligo), coal tar, and all-*trans* retinoic acid [35].

CYP3A4 is not expressed constitutively in the proliferating human skin keratinocyte but is induced by dexamethasone. In contrast, CYP3A5 mRNA is expressed constitutively [41].

8.3.2 Non-CYP Enzymes

This category includes phase I (e.g., aldehyde oxidase) and phase II DMEs that are involved in metabolic reactions including oxidation, reduction, hydrolysis, hydration, and group transfer. Extrahepatic non-CYPs DMEs include transferases, hydrolases, oxidases, dehydrogenases, reductases, peroxidases, and glucuronidase. These enzymes convert drugs into active/reactive/inactive metabolites in extrahepatic tissues and are essential for clearance and pharmacological activity of xenobiotics and are also responsible for the drug-induced toxicity.

8.3.2.1 Transferases. Transferases catalyze the transfer of functional groups from a donor to an acceptor molecule. These enzymes play a crucial role in converting electrophilic metabolites produced by phase I enzymes (e.g., CYPs) into less or nontoxic products [211–214]. Metabolic reactions catalyzed by transferase enzymes are shown in Fig. 8.3.

8.3.2.1.1 UDP-Glucuronosyltransferases. UDP-glucuronosyltransferases (UGTs) are located in the endoplasmic reticulum of mammalian cells and detoxify xenobiotics (e.g., therapeutic drugs, carcinogens and environmental pollutants) as well as endogenous compounds (e.g., bilirubin, bile acids, thyroid hormones and steroid hormones) [50,215]. About 40–70% of clinically used drugs are subjected to glucuronidation, resulting in hydrophilic products with low pharmacologically activity [216]. In humans, families of UGTs reported are UGT1, UGT2, UGT3,

Figure 8.3 Metabolic reactions catalyzed by transferase enzymes.

and UGT8 [50,216]. UGT1A is involved in glucuronidation of NSAIDs, anticonvulsants, chemotherapeutics, steroid hormones, bile acids, and bilirubin. UGT2B isoforms, UGT2B7 and UGT2B15 metabolize endogenous substrates, including hydroxylated steroids and bile acids, and xenobiotics [50,217]. UGT3A1 uses UDP-*N*-acetylglucosamine as a substrate to glycosidate xenobiotics, while UGT3A2 uses both UDP-glucose and UDP-xylose to glycosidate a broad range of substrates, including 4-methylumbelliferone, 1-hydroxypyrene, bioflavones, and estrogens [54]. UGT3A1 contributes in the metabolism and elimination of ursodeoxycholic acid for ameliorating the symptoms of cholestasis or dissolving gallstones [53]. UGT3A2 has a more selective role in protecting organs from toxins [54]. UGT8 converts UDP-galactose to galactosidate ceramide, an important step in the biosynthesis of glycosphingolipids and cerebroside [53,218]. These enzymes are distributed in the liver, GIT, lungs, kidneys, brain, placenta, reproductive organs, and so on [43,219]. The highest activity is reported in kidneys, followed by GIT and lungs [220].

The isoforms of UGTs expressed in human GIT are UGT1A1, UGT1A3, UGT1A4, UGT1A5, UGT1A6, UGT1A7, UGT1A8, UGT1A9, UGT1A10, UGT2A1, UGT2B4, UGT2B7, UGT2B10, UGT2B11, UGT2B15, and UGT2B28. UGT1A7 is prominently expressed in upper GIT, while UGT1A8 exists in the lower GIT [219]. The UGTs present in human esophagus are UGT1A7, UGT1A8, UGT1A9, UGT1A10, UGT2B7, UGT2B10, and UGT2B15. In stomach, the isozymes reported are UGT1A7, UGT1A10,

and UGT2B28. The subtypes, UGT1A1, UGT1A3, and UGT1A6, exhibit polymorphisms in stomach. Most of the UGTs present in the duodenum exhibit polymorphism (viz UGT1A1, UGT1A3, UGT1A4, UGT1A6, UGT1A8, UGT2B4, UGT2B7, and UGT2B15), except UGT1A10 and UGT2B28. In both jejunum and ileum, UGT1A10, UGT2B15, and UGT2B28 are the predominant DMEs, while UGT1A3 is additionally expressed in the jejunum. Expression of UGT isoforms UGT1A1, UGT1A3, UGT1A4, UGT1A6, UGT1A8, UGT1A9, UGT1A10, UGT2B7, UGT2B10, and UGT2B15 are highest in the colon [43,221,222].

Gregory *et al.* [219] reviewed literature and report that glucuronidation of bilirubin is catalyzed by UGT1A1 in the GIT and this isoform is involved in the conjugation of endogenous compounds (e.g., retinoic acid and estrogens) and xenobiotics. The isozymes, UGT1A5, UGT1A6, and UGT1A7, are involved in conjugation of xenobiotics, although their role in conjugating endogenous substrates is not yet established. The subtypes, UGT1A8, UGT1A9, and UGT1A10, are responsible for conjugation of mycophenolic acid and environmental pollutants such as PAHs. Tertiary amine drugs are conjugated by UGT1A4, oestrone by UGT1A3 and UGT1A10, while UGT2B4 and UGT2B7 are primarily involved in catalysis of hyodeoxycholic acid glucuronidation [223,224].

In human pulmonary system, the only UGT1A enzyme reported is UGT1A5 [43,225,226]. UGT1A6 and UGT1A8 are expressed in the larynx; UGT1A7 and UGT1A10 in the tongue, tonsils, floor of mouth, larynx, and esophagus; while UGT2B4 and UGT2B17 exhibit significant levels of expression through the aerodigestive tract [227]. UGT2A1 is prevalent in the aerodigestive tract, with highest expression in the lungs followed by trachea > tonsil > larynx > colon > olfactory tissue [43,225,226]. It provides protection against cancer by neutralizing tobacco carcinogens (PAHs, including 1-hydroxy benzo(α)pyrene, benzo(α)pyrene-7,8-diol, and 5-methylchrysene-1,2-diol) [226]. In other studies, UGT2B4, UGT2B11, and UGT2B17 have been shown to be present in the human bronchial epithelial cells [225,228].

The activity of UGT enzymes in the human kidneys is highest in PCT and DCT cells. For example, the propofol glucuronidation rate is higher in kidney than liver because of relative higher expression of UGT1A8 and UGT1A9 [43,45]. The human kidneys have low levels of UGT1A1 and UGT1A6 [49]. UGT1A9 and UGT2B7 are involved in the metabolism of endogenous and exogenous substances, which can result in renal drug–endobiotic interactions [229].

In the human brain, UGT1 is expressed in cerebellum and involved in glucuronidation of serotonin [230]. UGT1A6 is responsible for glucuronidation of propofol in the brain [231]; UGT2A1 is involved in glucuronidation of odorant compounds such as monoterpenoids, aliphatic alcohols, phenols, and coumarins and UGT2B7 metabolizes opioids and their metabolites (e.g., 3- and 6-hydroxyl morphine) [232,233]. UGT activity has been observed in the stratum corneum of the human skin [48].

8.3.2.1.2 *N*-Acetyltransferases. *N*-Acetyltransferases (NATs) are directly involved in *N*-acetylation of xenobiotics, such as aromatic and heterocyclic amines as well as drugs such as mesalamine (5-aminosalicylic acid, 5-ASA), isoniazid, sulfamethazine, and sulphasalazine [234–237]. Arylhydroxylamine metabolites generated by CYPs also undergo acetylation by NATs [234,235]. These enzymes have a role in the biotransformation of carcinogens and are inhibited by anticancer drugs, such as cisplatin and

tamoxifen [235]. NAT1 activity is increased in human cancer cells and can be induced by trichostatin A and inhibited by caffeic acid, ferulic acid, and gallic acid [238,239]. A well-known nonselective CYP inhibitor, 1-aminobenzotriazole, acts both as a substrate and an inhibitor of NAT1 [240]. The second human isoform, NAT2, is involved in *N*-acetylation of carbocyclic arylamines, such as 4-aminobiphenyl and β -naphthylamine [241]. Paracetamol, scopuletin, and curcumin [239,242] are reported to be inhibitors of NAT2.

NAT1 is widely distributed in the human body, whereas NAT2 is expressed predominantly in the intestine and liver [243]. In the intestine, both NATs are expressed in the GIT from esophagus to colon [55]. NAT2 is predominantly present in epithelial cells of the human intestine and involved in activation of compounds passing through this organ. The lung and urothelium of the urinary bladder express NAT1 and NAT2, while these are not expressed in the human kidneys [55,243]. In the human brain, the homologous enzymes NAT8L and NAT14 are involved in *N*-acetylaspartate synthesis [244]. NAT1 is expressed in human skin epidermal keratinocytes [56].

8.3.2.1.3 Glutathione *S*-Transferases. Glutathione *S*-transferases (GSTs) utilize glutathione (GSH) to form conjugates with a wide range of structurally different electrophilic substrates. This conjugation provides protection against cellular/organ toxicity [245]. GSTs are induced by diverse chemical compounds, such as isothiocyanates (such as benzylisothiocyanate, allylisothiocyanate, and sulforaphane), phenobarbital, 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene, pregnenolone-16 α -carbonitrile, 3-methylcholanthrene, 2,3,7,8-tetrachloro-dibenzo-*p*-dioxin, BNF, butylated hydroxyanisole, ethoxyquin, oltipraz, fumaric acid, coumarin, dexamethasone, thiazolidinediones 1-[2-cyano-3,12-dioxooleana-1,9(11)-dien-28-oyl]imidazole, 12-*O*-tetradecanoylphorbol-13-acetate, glyphosate, citrus triterpenoids (nomilin, isoobacunoic acid, and deacetyl nomilin), rambo (0.6% permethrin), cinnamon, cardamom, protocatechuic acid, myristicin, and so on [246–255]. The gene expression of GSTs is mediated by multiple receptors, viz, constitutive androstane receptor (CAR), PXR, AhR, nuclear factor E2 related factor (Nrf2), peroxisome proliferator-activated receptor- α/γ (PPAR α/γ), and CAATT/enhancer-binding protein (C/EBP) β [249,256,257]. Caffeic acid phenethyl ester selectively inhibits GSTs in the presence of tyrosine [258].

The mammalian GSTs have been very well characterized and classified as GST- α (GSTA), GST- μ (GSTM), GST- π (GSTP), and GST- θ (GSTT) subtypes based on structural conformation of protein, immunological identity and their susceptibility to inducers and inhibitors [245,259]. The GST isozymes reported in humans are GSTA1-4, GSTM1-5, GSTP1, GSTT1, and GSTT2 [260]. GSTA1, GSTA2, GSTM1, GSTM2, and GSTP1 are inhibited by polyphenolic compounds, such as ellagic acid and curcumin. GSTM1 and GSTM2 are also inhibited by genistein, kaempferol and quercetin [261].

GSTAs, GSTMs, and GSTPs are mainly expressed in the human GIT [262,263]. Overall, the activity of GSTs and expression of GSTA in the GIT increases in the following order: duodenum > stomach > sigmoid colon > transverse colon [58]. GSTA4, GSTM3, and GSTT1 are organ specific and located in the small intestine [148]. Duodenum shows higher GST activity than the colon [264]. GSTPs are highly expressed in the stomach, and their expression decreases from the proximal to distal direction [58]. The contents of GSTA and GSTP in the stomach are 4.5 ± 0.5 and $16.5 \pm 0.7 \mu\text{g/mg}$ and in duodenum are 20.0 ± 0.7 and $11.2 \pm 0.5 \mu\text{g/mg}$, respectively [58]. The main role of

GSTs in GIT is to detoxify electrophilic compounds ingested with foods (e.g., quinones and 4-hydroxyalk-2-enals), dietary supplements, and orally administered medicaments [265]. There is a report where 2(3)-*tert*-butyl-4-hydroxyanisole (BHA) induced GST by 2- and 15-folds in the mice stomach and small intestine, respectively [266]. PAHs and phenobarbital also induce GST in the intestine [267].

Multiple GSTs are expressed in the human lungs [268]. The GSTM isoforms, GSTM1 and GSTM3, are collectively expressed at 89.3 ± 27.8 ng/mg and GSTP1 at 762 ± 27.9 ng/mg. The combined expression of GSTA1 and GSTA2 in the lung is 80.8 ± 17.6 ng/mg [269]. Similar to GIT, GST expression in the lungs is induced by BHA, providing protection against lung cancer induced by PAHs [266]. GSTA, GSTM, and GSTP are expressed in the human kidneys and GSTA isoforms are highly expressed (50–70%) in the PCT, loop of Henle, and CD. GSTM and GSTP isoforms are expressed in DCT, Bowman's capsule, and CD [31,67,270]. GST isozymes in kidney are inhibited competitively by bromosulphophthalein and noncompetitively by bilirubin and haematin [60]. GSTM3, GSTM5, and GSTP are expressed in the human brain. GSTP is mainly localized in choroid plexus, pia-arachnoid, tanycytes, astrocytes, and ependyma of the brain, while GSTM3 is localized in astrocytes [61,271,272].

The reported activity of GSTs in epidermis, dermis, and whole skin is 27.5 ± 2.8 , 44.2 ± 3.0 , and 48.3 ± 3.05 nmol conjugate/min/mg protein, respectively [64]. GSTA, GSTM, and GSTP are expressed in the human skin cytosol, where GSTM is involved in detoxification of environmental toxicants that lead to skin allergies [64,65,273]. GSTP mRNA is expressed in cultured keratinocytes and fibroblasts of the human skin [274].

8.3.2.1.4 Sulfotransferases. Sulfotransferases (SULTs) are responsible for *O*- and *N*-sulfation of xenobiotics. Sulfation of molecules usually increases water solubility, often accompanied by a decrease in biological activity. SULTs are present either as membrane-bound or cytosolic enzymes. Membrane-bound SULTs are responsible for the sulfonation of peptides, proteins, lipids, and glycosaminoglycans, while cytosolic SULTs metabolize endogenous steroids, bile acids, neurotransmitters, and xenobiotics [275]. Three families of SULTs, that is, SULT1 (SULT1A1, SULT1A3, SULT1B1, SULT1C1, SULT1C2, SULT1C3, and SULT1E1), SULT2 (SULT2A1 and SULT2B), and SULT4 (SULT4A1) have been identified in humans, and SULT3 has primarily been reported in zebra fish [276–279].

SULT1 and its subtypes are responsible for the sulfonation of planar phenolic molecules such as estradiol, thyroid hormones, and xenobiotics [280]. SULT1A1, SULT1A3, SULT1C1, and SULT1E1 are involved in the sulfation of small neutral phenols, monoamine neurotransmitters, *N*-hydroxy-2-acetylaminofluorene, and 17 β -estradiol [280–283], respectively. SULT1C2 catalyzes sulfonation of thyroid hormone [284]. SULT2s are responsible for the sulfonation of hydroxyl groups of steroids, such as androsterone, allopregnanolone, and dehydroepiandrosterone [280]. For example, SULT2A1 metabolizes 3 α - and 3 β -hydroxysteroids as well as aliphatic hydroxyls of xenobiotics, whereas SULT2B1 is involved in selective sulfonation of 3 β -hydroxysteroids [281].

After the liver, human intestine has been reported to have highest SULTs activity, followed by the lungs and the kidneys [220,285]. The SULT subtypes reported in the human intestine are SULT1A1, SULT1A3, SULT1B1, SULT1E1, and SULT2A1, with the order of expression being: SULT1B1 (2400 ± 1300 ng/mg) > SULT1A3

(2000 ± 1100 ng/mg) > SULT1A1 (1300 ± 650 ng/mg) > SULT1E1 (490 ± 470 ng/mg) > SULT2A1 (390 ± 130 ng/mg) [286]. SULT1C2 is identified at mRNA level in the adult stomach [278]. The total expression of SULTs in the human intestine cytosol has been reported to be 7800 ± 4600 ng/mg, higher than their expression in the liver (5960 ± 1400 ng/mg) [286]. SULT1A1, SULT1A3, and SULT1B1 are expressed throughout the GIT; SULT1C1 is found in the stomach, while SULT1E1 and SULT2A1 are detected in the jejunum, ileum, and colon [68]. SULTs exhibit intersubject variability and do not exhibit any consistent trend across the intestine. In some subjects, SULT expression is higher in the central part, while in others it is higher at either end of the intestine [287,288]. SULTs are induced by methotrexate in Caco-2 cells and by tamoxifen in the rat intestine [289,290]. Isoetharine, isoprenaline, ethinyloestradiol, and paracetamol undergo sulfate conjugation in GIT [236].

SULT1A1, SULT1A3, SULT1B1, SULT1E1, and SULT2A1 have been detected in the human lungs. While total content of SULTs in the lung is reported to be 290 ± 130 ng/mg, the individual contents of SULT1A1, SULT1A3, SULT1B1, SULT1E1, and SULT2A1 subtypes are 60 ± 50 , 60 ± 80 , 40 ± 20 , 110 ± 110 , and 30 ± 20 ng/mg, respectively [286]. SULT1C3 is present in the fetal lungs [278]. In the human kidneys, high concentration of SULTs is reported in the cytoplasm of PCT and specific subtypes are expressed in CD and medulla [31]. Total SULT content in kidney is 430 ± 270 ng/mg. The expression of SULT1A1, SULT1A3, SULT1B1, and SULT2A1 is 170 ± 90 , 120 ± 70 , 130 ± 110 , and 5 ± 10 ng/mg, respectively, whereas expression of SULT1E1 in kidney is below the limit of quantitation [286]. SULT1C2 and SULT1C3 are expressed in the fetal kidney and SULT1C2 in the adults' kidneys [278].

Human brain expresses SULT1A1, SULT1A3, SULT1C2, SULT1E1, SULT2A1, SULT2B1, and SULT4A1 [69–72]. SULT1A1 is located in cytosol of the cerebellum, occipital, and frontal lobes, whereas SULT1A3 is present in cytosol of superior temporal gyrus, hippocampus, and temporal lobe. SULT1A1 is involved in the metabolism of small phenols and SULT1A3 metabolizes catecholamine neurotransmitters [70]. The location of SULT1E1 and SULT2B1 in the human brain is not specified [71,291]. SULT4A1 is located in the cortex, substantia nigra, cerebellum, pituitary, and brainstem; hence, it regulates functions and neurochemistry of different regions of the brain [72].

SULTs are present in the human scalp skin and skin fibroblasts [292,293]. The subtypes include SULT1A1, SULT1A3, SULT1E1, and SULT2B1 [73,74]. SULT2B1b is localized in the granular layer of skin epidermis and involved in synthesis of cholesterol sulfate, which is a critical regulator of keratinocyte differentiation and desquamation, and is a well-known mediator of barrier homeostasis [294,295]. Parabens inhibit SULTs, leading to prolonged estrogenic effects in skin, thus providing antiaging benefit [296].

8.3.2.1.5 Other Transferases. Carboxyltransferase (CT), thiopurine *S*-methyltransferase (TPMT), catechol-*O*-methyltransferase (COMT), and γ -glutamyltransferase (γ -GT) have been detected in extrahepatic sites. CT is expressed in PCT of the kidney and is inhibited by nonsteroidal anti-inflammatory drugs (NSAIDs) [31]. TPMT, a cytosolic enzyme, is expressed in RBCs, kidneys, lungs, and brain, apart from the liver and is responsible for the *S*-methylation of thiopurines such as 6-mercaptopurine, azathioprine, and 6-thioguanine [297,298]. Naproxen, mefenamic acid, and tolfemic acid are noncompetitive inhibitors of this DME [216].

COMT is a phase II enzyme that is highly expressed in liver, kidneys, intestine, and brain (postsynaptic neuron) in both cytoplasmic-soluble and membrane-bound forms [216] and is mainly expressed in the right inferior frontal gyrus and intraparietal sulcus of the brain [75,299]. Compounds with a catechol moiety, for example, catecholestrogens and catechol-containing flavonoids, are substrates of COMT. It introduces the methyl group in catecholamine, which is donated by *S*-adenosyl-L-methionine (SAM) [299]. COMT is involved in inactivation of catecholamine neurotransmitters, viz, dopamine, epinephrine, and norepinephrine, which can ultimately lead to behavioral problems, psychiatric disorders, chronic pain, and cancer [216,300,301]. The enzyme also plays a key role in metabolism of 3,4-dihydroxyphenyl-L-alanine (L-DOPA) [302]. Other specific reactions catalyzed by COMT include conversion of dihydroxyphenylethylene glycol (DOPEG) to methoxyhydroxyphenylglycol (MOPEG), and 3,4-dihydroxymandelic acid (DOMA) to vanillylmandelic acid (VMA) [303]. Entacapone increases bioavailability of L-DOPA by inhibiting COMT both peripherally and centrally and also by blocking conversion of dopamine into 3-methoxytyramine [216,304].

γ -GT is present in lungs, kidneys, brain, spleen, heart, and seminal vesicles [77,305–309]. This enzyme is primarily expressed in the PCT of kidney, which plays an important role in the transport of amino acids through a sequence of reactions forming a “gamma-glutamyl cycle” [310]. This enzyme also releases glutamate from drug-GSH adducts, leaving behind conjugates, which cause nephrotoxicity. It is irreversibly inhibited by acivicin [305].

8.3.2.2 Epoxide Hydrolases. Epoxide hydrolases (EHs) are phase I enzymes that metabolize exogenous and endogenous epoxides to vicinal diols, which are subsequently eliminated in a conjugated form [311,312]. EH enzymes have broad substrate specificity, including epoxide derivative of PAHs, anticonvulsant drugs, and steroids. On the basis of their molecular weights, subcellular localization, and substrate specificity, these are classified into five subgroups, viz, hepoxilin EH, leukotriene A4 hydrolase, cholesterol EH, microsomal EH, and soluble epoxide hydrolase (sEH) [312]. These have been subject of intensive investigations because their inhibition protects heart, brain, and kidneys against injury [80,313–316]. EHs are expressed in bronchial epithelial cells of lung and provide protection against development of lung cancer by hydrolyzing carcinogenic products of PAHs [317]. Lung EHs metabolize epoxytetraenoic acid (EET), which is responsible for blood pressure regulation [318]. Low levels of this enzyme have been reported in cytosolic fractions of the kidney [78]. EHs are differentially expressed in cerebral blood vessels and brain parenchyma, demonstrating their involvement in metabolism of vasodilator EETs into inactive diol metabolite in the brain [79,319]. EHs are found in epidermis, dermis, epithelial cells, and fibroblasts in the human skin [81–84]. These are reported to metabolize benzo(α)pyrene-4,5-oxide and *trans*-stilbene oxide in rat skin microsomes [320].

8.3.2.3 Flavin-Containing Monooxygenases. CYPs and flavin-containing monooxygenases (FMOs) have partially overlapping substrate specificities, although they may or may not generate the same metabolites. For example, FMOs exhibit highest catalytic activity toward pesticides, such as carbophenothion, methiocarb, and aldicarb and result in the generation of a sulfone metabolite [321]. In comparison, these pesticides are metabolized by CYPs into sulfoxide and sulfone [322]. Apart from qualitative and quantitative differences in the generation of metabolites, FMOs

and CYPs also exhibit differential stereoselectivity [323,324]. These enzymes are mainly involved in the metabolism of nucleophilic xenobiotics that contain nitrogen, sulfur, and phosphorous heteroatoms, for example, trimethylamine, sulindac, and methionine [88,325–328]. FMOs are of five subtypes, viz FMO1, FMO2, FMO3, FMO4, and FMO5 [329]. Their expression varies across extrahepatic tissues.

The relative expression of FMO subtypes in the human intestine is in the following order: FMO5 > FMO2 > FMO1 > FMO4 > FMO3 [86]. FMO1 is expressed in the human small intestine to a level of 2.9 ± 1.9 pmol/mg microsomal protein [329]. In the human lungs, FMOs are located in nonciliated bronchiolar epithelial (Clara) cells [330]. Among these, FMO2 is specifically expressed in lung, and primary amines and alkyl sulfides are important substrates for it [331,332]. The relative expression of FMO3, FMO4, and FMO5 in the human lungs as compared to the liver is ~4.5%, ~7% and ~4%, respectively. The overall order of expression of FMO subtypes in lung is FMO2 > FMO5 > FMO3 > FMO4 > FMO1 [86].

The primary site of the expression of FMO1 and FMO4 is the human kidneys [87]. Reported expression levels of FMO1, FMO3, and FMO5 in the human kidneys are 5.8 ± 2.3 , 0.5 ± 0.4 , and 2.4 ± 1.4 pmol/mg, respectively [96]. The expression of FMO1 varies from 5.0 ± 1.7 to 7.7 ± 2.4 pmol/mg of protein. It is involved in the metabolism of nitrogen- and sulfur-containing nucleophiles [96]. In human kidneys, FMO3 has very low expression (~3.7% of liver), while FMO4 is expressed moderately [93]. Renal FMOs are involved in the biotransformation of 5-HT₃ antagonists, viz, tropisetron and meperidine, into *N*-oxide metabolite [86,333]. In brain, FMOs are localized predominantly in neuronal cell bodies in magnocellular reticular nuclei, colliculi, and substantia nigra with relatively constant expression [88]. These enzymes are responsible for the metabolism of CNS drugs, for example, imipramine, fluoxetine, and chlorpromazine [334]. Relative expression of FMO subtypes in the human brain is in the order of FMO2 > FMO5 > FMO4 > FMO3 > FMO1 [86]. In the rat brain, FMOs metabolize *N,N*-dimethylaniline, methimazole, thiabenzamide, and antidepressant drugs such as imipramine and fluoxetine [88,335]. FMO1 and its polymorphs have potential influence on nicotine metabolism and hence, modulate its concentration in the brain [87,336].

In the skin, FMOs are localized in the epidermis, sebaceous glands, and hair follicles, with their basic role being detoxification of xenobiotics to which the skin is exposed [94]. FMO1 is expressed in epidermis and dermis and FMO3 in dermis, while FMO4 and FMO5 are expressed almost equally in total skin, dermis, and epidermis [89,94,95]. Another study has also reported the presence of FMO1, FMO3, FMO4, and FMO5 in the human skin, and these subtypes were found to play an important role in the metabolism of phorate [337].

8.3.2.4 Monoamine Oxidases. Monoamine oxidases (MAOs) are involved in the oxidative deamination of a range of monoamines, including 5-hydroxytryptamine (serotonin), histamine, and catecholamines (viz, dopamine, noradrenaline, and adrenaline), to yield respective aldehydes by liberating ammonia and hydrogen peroxide [338]. These enzymes are located predominantly in the outer membrane of mitochondria, with low concentrations associated with microsomal fractions [99]. MAOs are abundantly expressed in organs with direct exposure to the environment, for example, lungs, GIT, and liver [338]. In humans, MAO-A and MAO-B are expressed, with the order of expression of MAO-A being small intestine $\geq$ placenta $\geq$ lungs $\geq$ muscle > kidneys

> brain $\geq$ spinal cord $\geq$ meninges $\geq$ liver > spleen > adrenal glands, and MAO-B: small intestine > kidneys $\geq$ liver > adrenal glands > heart > spinal cord > lungs. The combined MAO activity in different parts of the brain is in the order: frontal cortex > locus coeruleus > temporal cortex $\geq$ posterior pensylvian cortex-supramarginal gyri > anterior pensylvian cortex-opercular gyri $\gg$ hippocampus and thalamus [97]. MAO-A is present in catecholaminergic neurons (cells of the substantia nigra, the locus coeruleus, and the periventricular regions of the hypothalamus); while predominant expression of MAO-B is in serotonergic neurons (dorsal raphe nucleus), astrocytes, lateral and posterior hypothalamic regions, and platelets [99,100]. These MAOs are nonselectively inhibited by stilbene-like derivatives [339]. In different organs, MAO-A is selectively inhibited by clorgyline, toloxatone, and cimoxatone, while MAO-B is inhibited by selegiline (L-deprenyl) [340–342]. The MAO enzymes are expressed in nerves around hair follicles, cutaneous nerve fibers beneath the epidermis, and human skin fibroblasts [101–104].

8.3.2.5 Additional Non-CYP Enzymes. β -Glucuronidase (β -Gluc), alcohol dehydrogenase (ADH), aldehyde dehydrogenase (ALDH), aldose reductase (AR), myeloperoxidase (MPO), and GSH reductase are additional non-CYP enzymes present in extrahepatic sites. β -Gluc is located in the brush border epithelium and microflora of human GIT, lung alveolar macrophages, spleen, and placenta [105,106,343,344]. It is responsible for the cleavage of glucuronide complexes and for the liberation of the active moiety for reabsorption, in cases, leading to enhanced drug action [49]. In gut, β -Gluc is responsible for the hydrolysis of exogenous and endogenous β -glucuronides produced in the liver by UGT (e.g., morphine glucuronide conjugates), aiding in enterohepatic reabsorption [105].

ADHs are cytosolic dimeric metalloenzymes involved in the metabolism of ethanol to aldehydes in the presence of nicotinamide adenine dinucleotide [118]. ADHs are located in the gingiva, tongue, esophagus, stomach, and colon in GIT. These do not show any specific pattern of expression from distal to proximal end of the human GIT but are highly expressed in esophagus and stomach [118]. They have also been reported to be expressed in the human lungs [107]. In the human kidneys, ADHs are mainly located in epithelial tubuli, glomeruli, and collecting tubules. Low content of ADHs is also reported in adrenal glands, neurons of the cerebral cortex, hypothalamus, infundibular stalk of the pituitary, and purkinje cells of the brain cerebellum [108,111]. In the human skin, ADH is localized in the epidermis, sebaceous glands, and hair follicles and is involved in detoxication and toxication of compounds that can cause allergic contact dermatitis, such as *trans*-cinnamaldehyde and *trans*-cinnamic alcohol [110,345].

Human ADHs have been divided into following five classes based on structural and catalytic features: Class I (α -ADH, β -ADH, and γ -ADHs); Class II (π -ADH), Class III (χ -ADH), Class IV (μ -ADH or σ -ADH), and Class V (resembles Class I, named as $\alpha\alpha$ -isozyme) [112,118,346]. Class I ADH mRNA is widely distributed in most tissues, including brain and placenta, although it is abundantly expressed in hepatic region and plays major role in the first-step metabolism of ethanol. The expression of Class II and Class V mRNA is mainly limited to hepatic tissues, with low mRNA concentrations of Class II detected in stomach, pancreas, and small intestine. Class V enzymes demonstrate similar distribution in fetal kidneys and small intestine. The distribution pattern of Class III mRNA is consistent with those of housekeeping enzymes, while expression of Class IV mRNA is restricted to the stomach [112].

ALDHs are responsible for the oxidation of aldehydes generated during retinoic acid biosynthesis and alcohol metabolism and also for the metabolism of amino acids, biogenic amines, steroids, lipids, carbohydrates, and drugs into their respective carboxylic acids [347]. Ten types of ALDHs (ALDH1-10) are known [115,118]. ALDH1, ALDH2, and ALDH6 are expressed in the gut; ALDH3 and ALDH7 in the lung; and ALDH4, ALDH6, ALDH7, and ALDH9 in the kidney [115]. In the GIT, ALDHs are located in gingiva, tongue, esophagus, and stomach. Like ADHs, these enzymes are also highly expressed in esophagus and stomach [118]. Expression of ALDHs in the lung is increased by carcinogenic aldehydes found in cigarette smoke [348]. In the kidney, ALDH enzymes are located in cortex tubules and provide protection against toxicity of aldehydic metabolites, for example, chloroacetaldehyde, a metabolic product of ifosfamide [349]. In the human brain, expression of ALDHs is in the order of spinal cord > corpus callosum > subthalamic nucleus > medulla > thalamus > amygdale > cerebral cortex > substantia nigra > hippocampus > caudate nucleus > temporal lobe > cerebellum > putamen > frontal lobe > occipital pole [350]. These are reported to be involved in metabolism of γ -aminobutyraldehyde [350]. ALDH enzymes are located in the epidermis, sebaceous glands, and hair follicles of the human skin and play an important role in the metabolism of exogenous aldehydes. ALDH1, ALDH2, and ALDH3 are detected in different regions of the human skin. ALDH1 and ALDH3 are predominantly localized in the epidermis and dermal appendages [117], while ALDH2 is localized in the epidermis and hair follicles of the human skin [120].

AR is a NADPH-dependent oxidoreductase enzyme that is involved in the reduction of a variety of aldehydes and carbonyls, including monosaccharides. Substrates for AR include isocortisol, isocorticosterone, aromatic aldehydes, arylalkylaldehydes, and so on [351]. It is primarily known to catalyze reduction of glucose to sorbitol, the first step in the polyol pathway of glucose metabolism. The second and last step in the pathway is catalyzed by sorbitol dehydrogenase, which helps in the oxidation of sorbitol to fructose [352]. The aldose reductase reaction, responsible for sorbitol production, is important for the function of various organs in the body. For example, fructose produced from sorbitol is used by the sperm cells and is also used as an energy source for glycolysis and glycconeogenesis [353]. Incidentally, AR is also linked with toxicities, e.g. there is persistent increase in glucose levels, like in diabetes. Being hyperosmotic, the presence of sorbitol increases pressure inside various organs and hence leads to retinopathy, nephropathy, neuropathy, and other diabetic complications [354–356]. Retinopathy is linked to the presence of AR in the mural cell of retina and lens in the eyes [357,358]. AR in the human small intestine is coded HSI-AR and is reported to catalyze the reduction of carotene [121]. In the human kidneys, AR mRNA is expressed in the papilla of epithelial, endothelial, interstitial, and thin limb cells, connecting tubules, cortical CDs, and medullary CD. Weak expression is reported in the outer medulla, cortex, Bowman's capsule, and the glomerular tuft [122]. This enzyme is also reported in the human brain and involved in catalysis of NADPH-dependent reduction of physiological and xenobiotic aldehydes [123].

MPO is a phase I peroxidase enzyme present in the lysosome of neutrophils and exists in high concentration in the lung [124]. MPO is involved in the activation of benzo(α)pyrene and aromatic amines in tobacco smoke to generate carcinogenic free radicals [124,359]. 4-Aminobenzoic acid hydrazide is a specific irreversible inhibitor of MPO [360].

8.4 FACTORS INFLUENCING EXPRESSION OF EXTRAHEPATIC DMEs

Genetic polymorphism, age, gender, pathophysiological conditions, inborn errors in metabolism, environmental pollutants, and food contribute to the expression and activity of DMEs.

8.4.1 Genetic Polymorphism

Genetic polymorphism is defined as differential expression of genes, that is, having multiple alleles in different populations. Polymorphism in genes may be inherited and/or occur because of environmental factors. The study of alleles provides information on differences in levels of enzymes, which also helps to predict interpopulation variation in susceptibility to diseases. Genetic polymorphism of CYP2C9, CYP2C19, CYP2D6, CYP3A4, and CYP3A5 alter their activities, resulting in diminished efficacy or increased toxicity of certain drugs [361,362]. For example, poor metabolizing phenotype of CYP2D6 results in dose-dependent toxicity of debrisoquine, perhexilene, and phenacetin, while the extensive metabolizing phenotype leads to therapeutic failure of codeine and selected antidepressant drugs in different populations [363]. Alterations in genes including CYP1A1, CYP1A2, CYP1B1, CYP2A6, CYP2A13, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4, GSTM1, GSTT1, GSTP1, NAT, and SULT have the potential to contribute to toxicities, including metabolic activation of procarcinogens, leading to development of carcinogenicity in extrahepatic organs [364–366]. Table 8.2 summarizes studies on genetic polymorphism of DMEs in extrahepatic tissues, mainly with relevance to the development of cancer.

8.4.2 Age and Gender

The expression of DMEs, especially CYPs, is greatly influenced by both age and gender. Usually, extrahepatic expression of CYPs is lower in neonatal and pediatric tissues, relative to the adults, for example, CYP1A1 is not found in kidneys of neonates [403]. In the fetal duodenum, CYP3A4 activity is absent, and a statistically significant increase in expression was observed from two weeks to 17 years of age [404]. The expression of duodenal CYP3A4 is maximum in young females and decreases by around 20% in postmenopausal women [405]. In the kidney, CYP3A4 and CYP3A5 are present at gestational age of eight weeks [406]. MAO-B activity is low at birth, remains constant in childhood, and then increases with age [407]. The level of EHs in fetal lungs is comparatively lower than the adult lungs [408]. Table 8.3 lists additional instances where DMEs are higher in fetus and neonates than adults.

Among the examples of the influence of gender, CYP2E1 is less active in women than men, with no gender differences in activities of CYP1A2, CYP2C19, CYP2D6, and CYP3A4 [412]. However, Paine *et al.* [405] reported higher CYP3A4 expression in the small intestine of men than women. In different studies on smokers, women had higher expression of CYP1A1, CYP1A2, and CYP3A4 in the lung as compared to men [413–415]. Higher CYP3A4 expression was associated with the metabolism of major lung procarcinogens/carcinogens to generate reactive oxygen species (ROS) or reactive metabolites, thus exacerbating the susceptibility to carcinogenicity [415].

Both age- and gender-dependent differences have also been reported in the expression and activity of GSTs, with women having higher expression in the distal colon, as

TABLE 8.2 Relationship of Genetic Polymorphism of DMEs with the Development of Cancer in Extrahepatic Organs

Enzyme	Organ with Expression of Polymorphic Gene	Genotype/Allele	Outcome	Population (State/Country)	References
CYP1A1	Esophagus	<i>CYP1A1</i> exon 7 polymorphism(Val/Val)	Slightly increased risk of cancer	Not specified (Taiwan)	367

TABLE 8.3 Examples of Higher Expression of DMEs in Early Years of Human Life as Compared to Adulthood

Enzyme	Age Group	Organ(s)	Anticipated Outcome	References
CYP1A1	Fetus	Brain	—	409
	8 and 21 weeks gestational age	Lung	—	403
CYP1B1	Fetus	Kidney, thymus, and lung	—	403,409,410
CYP2B6	Neonates	Kidney	Renders neonates more vulnerable to ifosfamide induced nephrotoxicity	404
CYP2R1	Fetus	Brain	—	409
CYP2W1	Fetus	Lung and kidney	—	409
CYP3A4	Neonates	Kidney	Renders neonates more vulnerable to ifosfamide-induced nephrotoxicity	404
GSTP1	Fetus and neonates	Lung	—	411
GSTA1/A2	20 Weeks gestational age	Kidney (nephron)	—	411
SULT1A3	Fetus (18–25 weeks)	Kidney	—	411
FMO1	Fetus	Brain	—	86

compared to men [264]. In this study, the GST activity increased with age in women, while it remained constant in men. Reversibly, expression of GSTM1 did not change in women with age but decreased in men on aging. Also, expression of GSTP1 in distal and proximal colon of women (50–70 years) was higher than men and women below 50 years.

The expression of ADHs in gastric mucosa of women has been reported to be less than that of men. ADH activity decreased in men with increasing age, while values in women between 41 and 60 years of age were higher than those between 20–40 and 61–80 years. In men of 40–50 years, gastric ADH level decreased significantly and became almost similar to that of women of the same age. There was reduced ADH activity in men between 20 and 40 years, who consumed large quantities of alcohol [416,417].

8.4.3 Pathophysiological Conditions and Inborn Errors of Metabolism

The expression of DMEs in extrahepatic organs can be altered by disease states, and certain diseases such as cancer are provoked because of alterations in the enzyme levels. Inborn errors of metabolism result in expression of inactive enzymes [418]. CYPs may be downregulated because of (i) inflammation in response to tissue damage, (ii) infection, (iii) burns, (iv) trauma, (v) tumors, and (vi) autoimmune diseases. Infectious agents, such as hepatitis A, influenza A/B, herpes simplex, HIV, helicobacter pylori, plasmodium falciparum, and so on, also modulate CYP-dependent biotransformation of drugs in humans [418]. Table 8.4 lists disease conditions and inborn errors

TABLE 8.4 Changes in the Expression of Enzymes in Extrahepatic Organs as a Result of Pathophysiological Conditions and Inborn Errors of Metabolism

Organ(s)	Disease/Infecting Agent/Inborn Error of Metabolism	Enzyme	Expression of mRNA/Proteins	References
Esophagus	Squamous cell carcinoma	CYP1A1, CYP1A2, CYP2E1, CYP1B1, CYP2C8, and CYP2C9	Expressed only in tumor cells	419–421
		CYP2B6 and CYP3A5	Increase	419–421
		CYP3A4	Decrease	419
	Adenocarcinoma	CYP2J2	Expressed only in tumor cells	419
Stomach	Foveolar epithelium with intestinal metaplasia of stomach	CYP3A4	Increase	422
	Gastric carcinoma	CYP1B1 and CYP2J2	Expressed only in tumor cells	419,420
		CYP2W1	Increase	419,420
	Chronic gastritis (caused by <i>Helicobacter pylori</i>)	ADH	Decrease	423,424
Small and large intestine	Celiac disease	CYP3A	Decrease	425–427
		CYP1A	Decrease	427
	Crohn's disease	CYP3A4 and CYP3A5	Increase	425
	Inflammatory bowel disease	CYP3A4 and CYP3A5	Increase	419
	Colon adenocarcinoma	She	Decrease	428
		CYP1B1	Expressed only in tumor cells	419,420

Brain	Glial cell tumor	CYP1B1	Expressed only in tumor cells	419
	Alzheimer's disease	CYP27 and CYP46	Redistribution	15
	Parkinson's disease	CYP2D6	Decrease	15

Heart	Inflammation followed by ischemic brain injury (astrocytes of hippocampus)	CYP2E1	Increase	429,431
	Inflammation due to trauma-evoked head injury	CYP1A1	Decrease	429,431
		CYP4F4 and CYP4F5	First decrease and then increase after two weeks	418
	Dilated cardiomyopathy	CYP1A1	Detected in right ventricle, ascending aorta, pulmonary aorta, and right atrium. In normal patients, it is detected only in left ventricle	11,12
		CYP2B6 and CYP2B7	Detected in right ventricle and aorta	11
		CYP4B1	Detected in right ventricle	11
		CYP2D6	Detected only in right ventricle	11
		CYP2C8 and CYP2C9	Induced following ischemic injury	432
	Different organs	CYP2D6	Decrease	418
	Inborn errors of metabolism with effect on different organs	CYP11A1, CYP11B1, CYP11B2, CYP17, and CYP21	Autosomal recessive disorder	3
	Vitamin-D-dependent rickets (bones)	CYP27B1 and 25-hydroxy D ₃ 1 α -hydroxylase	Autosomal recessive disorder	3
	Primary congenital glaucoma (eyes)	CYP1B1	Autosomal recessive eye disorder (deletions, insertions)	3
	Sjögren–Larsson syndrome (skin and nervous system)	ALDH10	Autosomal recessive disorder	3

of metabolism, which can alter expression of DMEs and defects in enzyme genes, respectively.

8.4.4 Food

Another category that influences expression of CYPs in various extrahepatic organs is food. For example, chronic intake of char-grilled meat induces CYP1A1 in the intestine, and this is linked with potentiating the risk of intestinal cancer [433]. The nature of food also affects GST expression, for example, GSTA and GSTP were induced in duodenum on intake of vegetables and GSTT1 in gastric mucosa was induced on the consumption of certain fruits. Citrus fruits induced GST activity in the rectal mucosa, and a brassica vegetable also leads to induction of GSTM1 [434]. However, no reports exist on food-dependent changes in colonic GST activity. A majority of commonly used food products, such as potato, onion, garlic, spices, rice, and bread, do not change DME activities significantly [58].

8.5 ROLE OF EXTRAHEPATIC DMEs IN BIOACTIVATION AND DEACTIVATION OF XENOBIOTICS

DMEs in extrahepatic organs play an important role in bioactivation of drugs/prodrugs/precancerogens and/or deactivation of drugs/metabolites/carcinogens. For example, terfenadine (a nonsedating antihistaminic prodrug) is metabolized by CYP3A4 in the intestine, to the active moiety, fexofenadine (Fig. 8.4). The active metabolite acts on H₁ receptors at different sites in the body, resulting in pharmacological activity [198]. Similarly, metabolism of cyclophosphamide is directly responsible for its therapeutic activity and also for toxicity. The initial activation step involves oxidation of the heterocyclic ring to produce 4-hydroxycyclophosphamide, which is in spontaneous equilibrium with its cyclic tautomer aldophosphamide. Acrolein is spontaneously eliminated from aldophosphamide to yield phosphoramidate mustard, an active alkylating agent. 4-Hydroxycyclophosphamide, acrolein, and phosphoramidate mustard in the presence of CYPs and other oxidative enzymes are responsible for the pharmacological activity as well as toxicity of the drug (Fig. 8.5) [435]. Another example is of sulindac, a sulfoxide prodrug, which is metabolized in kidney into inactive sulfone and bioactive sulfide (Fig. 8.6). The formation of

Figure 8.4 Bioactivation of terfenadine in the GIT.

Figure 8.5 Metabolism of cyclophosphamide in the lung.

Figure 8.6 Metabolism of sulindac in the kidneys [436].

the latter is reversible, therefore, the kidney rapidly interconverts active sulfide back to inactive sulfoxide [436]. The reaction is reported to be mediated in humans by kidney microsomal FMOs [437]. Similarly, codeine is metabolized into morphine by CYP2D6 in the brain (Fig. 8.7), which is responsible for the analgesic effect of the former [438]. Additional examples of bioactivation and deactivation of drugs in GIT, lungs, kidneys, and brain, along with their metabolites, are listed in Table 8.5.

Figure 8.7 Metabolic bioactivation of codeine in the brain.

8.6 SIGNIFICANCE OF EXTRAHEPATIC METABOLISM

The metabolism of drugs in extrahepatic organs results in alteration of systemic bioavailability and toxicity. Inhibition/induction of DMEs in extrahepatic tissues and organs by the drugs can alter pharmacokinetic/pharmacodynamics of other concomitantly administered drugs. These effects have significant impact on the overall clinical outcome of the therapy.

8.6.1 Bioavailability

The therapeutic action of a drug is determined by the dose achieved at the target site in the body. The latter in turn is determined by the amount of the substance absorbed, which further depends on its bioavailability. The bioavailability of drugs can be limited by their absorption from the GIT epithelium and/or through first-pass metabolism. Although the major site for the first-pass metabolism is liver, GIT is a significant contributor, as it presents a very large area for the metabolism, with numerous DMEs being expressed along its length. For example, Marier *et al.* [543] explored the contribution of rabbit liver and intestine on the elimination rate of different enantiomers of propranolol. At a concentration of $5.8 \mu\text{M}$, *R*(+) propranolol was metabolized faster in the intestine in comparison to the liver. Likewise, the bioavailability of inhaled drugs is significantly affected by their metabolism in the lung. In addition, factors such as age, sex, food, disease state, and interindividual variation were found to influence the bioavailability of drugs and xenobiotics, owing to increase or decrease in the expression of DMEs [544,545].

8.6.2 Toxicity

Drug-induced organ toxicity is not only dose-dependent but also a result of the generation of reactive metabolites, which include electrophiles and/or free radicals. The latter have the potential to interact with nucleophiles, such as DNA and proteins. The mechanism of reactive metabolite-induced toxicity is shown in Fig. 8.8 [546]. Toxicity can be significantly alleviated as a result of the binding of reactive metabolites to GSH, but once most of the GSH gets consumed, reactive metabolites exceed a limit, leading to significant toxic effects.

The wide distribution of DMEs in different organs provides the possibility for generation of reactive metabolites across the body and hence, the widespread toxicity.

TABLE 8.5 Examples of Drugs that Undergo Bioactivation and Deactivation in Extrahepatic Tissues

Organ	Substrate	DME	Metabolic Product(s)	Outcome/Significance	References
Gastrointestinal tract	Chlorpromazine	CYP	<i>S</i> -oxide, <i>N</i> -oxide, 7-hydroxyl, desmethyl, and didesmethyl chlorpromazine	Deactivation and first-pass metabolism	439,440
	Carbamazepine	CYP	10,11-Epoxy and 10,11- <i>trans</i> dihydrodiol carbamazepine	Deactivation and first-pass metabolism	441,442
	Astemizole	CYP	<i>O</i> -Desmethyl astemizole	Deactivation and first-pass metabolism	145
	Benzo(α)pyrene	CYP1A1	Benzo(α)pyrene-7,8-dihydrodiol	DNA adduct formation	443
	Astemizole	CYP2J2	Astemizole <i>O</i> -demethylation	First-pass metabolism	145
	Alprazolam	CYP3A4	Alprazolam-4-hydroxylation	Deactivation and first-pass metabolism	444,445
	Terfenadine	CYP3A4	Fexofenadine	Bioactivation	198
	Indinavir	CYP3A4	Oxidative metabolite	Deactivation	446
	Simvastatin	CYP3A4	—	Deactivation and first-pass metabolism	442
	Buspirone	CYP3A4	—	Deactivation and first-pass metabolism	442
	Carvedilol	CYP3A4	Oxidative metabolite	Biotransformation	447
	Diazepam	CYP3A4	—	Deactivation and first-pass metabolism	442
	Sirolimus	CYP3A4	Secorapamycin	Biotransformation	448
	Felodipine	CYP3A4	—	Deactivation and first-pass metabolism	442
	Clindamycin	CYP3A4	Clindamycin sulfoxide	Biotransformation	449
	Saquinavir	CYP3A4	—	Deactivation and first-pass metabolism	442
	Nicardipine	CYP3A4	—	Deactivation and first-pass metabolism	442
	Flurazepam	CYP3A4	Mono- and didesetyl flurazepam	Deactivation and first-pass metabolism	450
	Midazolam	CYP3A4 and CYP3A5	1'-Hydroxymidazolam	Deactivation and first-pass metabolism	444,451,452
	Verapamil	CYP3A4	—	Deactivation and first-pass metabolism	442
	Nifedipine	CYP3A4	Oxidized nifedipine	Deactivation and first-pass metabolism	444,453,454
	Nisoldipine	CYP3A4	BAY o 3199 and BAY r 9425	Biotransformation	455

(continued overleaf)

TABLE 8.5 (continued)

Organ	Substrate	DME	Metabolic Product(s)	Outcome/Significance	References
	Lovastatin	CYP3A4	6' β -Hydroxy and 6'-exomethylene lovastatin	Deactivation and first-pass metabolism	456,457
	Fentanyl	CYP3A4	<i>N</i> -Dealkylated fentanyl	Deactivation and first-pass metabolism	458
	Cyclosporine	CYP3A4	Hydroxylated and <i>N</i> -methylated cyclosporine	Deactivation and first-pass metabolism	459
	Tacrolimus	CYP3A4	13- <i>O</i> -Demethyl and 13,15- <i>O</i> -demethyl tacrolimus	Deactivation and first-pass metabolism	460
	Methadone	CYP3A4	2-Ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine, 2-ethyl-5-methyl-3,3-diphenylpyraline	Deactivation	461
	L- α -Acetylmethadol	CYP3A4	L- α -Acetyl- <i>N</i> -normethadol, L- α -acetyl- <i>N,N</i> -dinormethadol	Bioactivation	461
	Ebastine	CYP3A4	Desalkylebastine	Deactivation	462
	Ritonavir	CYP3A4	<i>N</i> -Demethylation, oxidation of methylthiazolyl, hydroxylation of isopropyl side chain, and 2-(1-methylethyl)thiazolylmethyl group	Biotransformation	463
	Pravastatin	CYP3A4 and CYP3A5	3' α , 5' β , 6' β -Trihydroxypravastatin, sulphated pravastatin, 3' α -iso-pravastatin.	Deactivation and first-pass metabolism	456
	Oxycodone	CYP3A4 and CYP3A5	<i>N</i> -Demethyled oxycodone	Deactivation and first-pass metabolism	464
	Prasugrel	CYP3A and carboxylesterase 2	Thiol-containing active metabolites	Bioactivation	465

Quinidine	CYP3A62	3-Hydroxy quinidine	Deactivation and first-pass metabolism	466
Amiodarone	CYP3A1, CYP3A2, and CYP1A1	Desethylamiodarone	Deactivation and first-pass metabolism	467
Benzamidoxime	Reductase	Benzamidine	—	468
Guanoxaben	Reductase	Guanabenz	—	468
Ethanol	ADH	Acetaldehyde	First-pass metabolism	469
Polychlorinated biphenylol	UGTs	Glucuronide conjugate	Deactivation	470
Bisphenol A	UGTs	Glucuronide conjugate	Biotransformation	471
Galangin	UGTs	Galangin glucuronide	Deactivation	472
Kaempferol	UGTs	Kaempferol glucuronide	Deactivation	472
Indomethacin	UGTs	Indomethacin glucuronide	Deactivation	473
Paracetamol	UGTs	Glucuronide conjugate	Deactivation	474
Salbutamol	UGTs	Glucuronide conjugate	Deactivation	462
Salmeterol	UGTs	Glucuronide conjugate	Deactivation	462
Bambuterol	UGTs	Glucuronide conjugate	Deactivation	462
Formoterol	UGTs	Glucuronide conjugate	Deactivation	462
Fenoterol	UGTs	Glucuronide conjugate	Deactivation	475
Losartan	UGTs	Glucuronide conjugate	Deactivation	476
1-Naphthol	UGTs	Glucuronide conjugate	Deactivation	477
Biochanin A	UGT	Glucuronide conjugate	Deactivation	478
Raloxifene	UGT	Glucuronide conjugate	Deactivation	478
Scutellarin	UGTs and β -glucuronidase	Scutellarein	Bioactivation	479
Baicalein	UGT and SULT	Glucuronidation and sulfation of baicalein	Biotransformation	480
Clioquinol	SULT1A3	Sulphated clioquinol	Biotransformation	481

(continued overleaf)

TABLE 8.5 (continued)

Organ	Substrate	DME	Metabolic Product(s)	Outcome/Significance	References
	Fenthion	FMO1	Fenthion sulfoxide	Biotransformation	325
	Methiocarb	FMO1	Methiocarb sulfoxide	Biotransformation	325
	Cefpodoxime proxetil	Choline esterases	Cefpodoxime	Bioactivation	482,483
	<i>O</i> -Isovaleryl- propranolol	Esterase	Propranolol	Bioactivation	484
	L-751,164 (prodrug of potent fibrinogen receptor antagonist)	Esterase	L-742,998 (active drug)	Bioactivation	485
	Glycovir	Esterase	SC-48334 (active metabolite)	Bioactivation	486
	Timolol maleate	Esterase	Timolol	Bioactivation	487
	Levobunolol	Ketone reductase	Dihydrolevobunolol	—	487
	5-Aminosalicylic acid	NAT	<i>N</i> -Acetyled-5-aminosalicylic acid	Deactivation	488
	Ambamide	Amine oxidase	<i>p</i> -Carboxybenzene sulphonamide	Deactivation	489
	Isoprenaline	COMT	<i>O</i> -Methyl isoprenaline	Deactivation and first-pass metabolism	490,491
	Terbutaline	Not defined	Sulphate conjugate	Deactivation and first-pass metabolism	492
	3-Chloro-1,2- propanediol fatty acid esters	Not defined	Hydrolytic metabolites	Detoxification	493
	Halofantrine	Not defined	Desbutylhalofantrine	Bioactivation	494
	Daidzein	Not defined	Equol	Bioactivation	495
	Cycloastragenol	Not defined	Glucuronide conjugates and oxidative metabolites	Deactivation and first-pass metabolism	496
	Hesperetin	Not defined	Hesperidin	Deactivation and first-pass metabolism	497

Pulmonary system	Enalapril	Not defined	Enalaprilat	Bioactivation	498
	Cyadox	Not defined	Cyadox-1-monoxide	Biotransformation	499
	Phorate	CYP	(+) Phorate sulfoxide	Detoxification	324,500
	Nilutamide	CYP	Amine and hydroxylamine metabolite	Reactive metabolite generation	501
	Benzo(α)pyrene	CYP1A1	Benzo(α)pyrene-7,8-dihydroepoxide	Metabolic activation by epoxide hydroxylase and CYP1B1 followed by the formation of DNA adducts, leading to lung cancer	502,503
	NKK	CYP1A1	Keto aldehyde (major), keto alcohol (minor)	Carcinogenic product	20
	3-Methylindole	CYP1A1, CYP2F1, CYP2A13, and CYP4B1	3-Methyleneindolenine	Alkylates DNA and induces cell death through apoptosis	504
	Benzo(α)pyrene	CYP1B1	Benzo(α)pyrene-7,8-dihydroepoxide	Carcinogenic product leading to mutation in <i>p53</i> gene in lung	503
	Benzo(α)pyrene-7,8-dihydroepoxide	EH	($\pm$)-Benzo(α)pyrene- <i>trans</i> -7,8-dihydrodiol	—	503
	($\pm$)-Benzo(α)pyrene- <i>trans</i> -7,8-dihydrodiol	CYP1B1	Benzo(α)pyrene-7,8-dihydrodiol-9,10-epoxide	Carcinogenic product leading to mutation in <i>p53</i> gene in lung	503

	Guanoxaben	Reductase	Guanabenz	—	468
	Propofol	UGT1A6	Propofolglucuronide	Deactivation	231
	Capsaicin	CYP	Vanillylamine, vanillic acid	Biotransformation	530
	Hesperetin	UGT	Hesperetin glucuronide	Biotransformation	531
	Fluroxypyr methyl ester	Esterase	Fluroxypyr	Acid metabolite	204
Skin	Fluroxypyr methylheptyl ester	Esterase	Fluroxypyr	Acid metabolite	204
	Amethocaine	Esterase	p-(Butyl)aminobenzoic acid	Biotransformation	532
	O-Acyl haloperidol ester	Esterase	Haloperidol	Bioactivation	533
	Acyclovir valerate	Esterase	Acyclovir	Bioactivation	534

	Sulfamethoxazole	NAT	<i>N</i> -Hydroxy and <i>N</i> -acetyl metabolites	Bioactivation	535
	Paraphenylene-diamine	NAT1	Monoacetyl paraphenylenediamine	Biotransformation	56
	Benzocaine	NAT	<i>N</i> -Acetylbenzocaine	Biotransformation	536
	Phorate	FMO	Phorate sulfoxidation	Biotransformation	337
	Triclosan	UGT	Glucuronide conjugate	Biotransformation	537
	Triclosan	SULT	Sulfate conjugate	Biotransformation	537
	Minoxidil	Phenol sulfotransferase	Minoxidil sulfate	Bioactivation	292,538
	Propranolol	Microsomes	4'-Hydroxypropranol	Biotransformation	539
	Theophylline	Microsomes	1,3,7-Trimethyluric acid and 1,3-dimethyl uric acid	Biotransformation	540
	Prednisolone farnesylate	Not specified	Prednisolone	Bioactivation	541
	TU-2100 [bis(<i>o</i> -carboxyphenyl ethyl ester) nonanedioate]	Not specified	—	Bioactivation	542
CVS	Glyceryl trinitrate	CYP3A4	NO	Biotransformation	16
	Isosorbide Dinitrate	CYP3A4	NO	Biotransformation	16
	Verapamil	CYP3A4,	Carbinolamine, <i>N</i> -formyl,	Biotransformation	92
		CYP3A5, CYP2C8, CYP2C18, CYP2D6 and CYP2E1	ahemiacetale, <i>N</i> -demethyl, <i>O</i> -demethylverapamil		

Abbreviations: AFB1, Aflatoxin B1; MeDDC, *S*-methyl *N,N*-diethyldithiocarbamate; MeDTC, *S*-methyl *N,N*-diethylthiocarbamate; NAPQI, *N*-acetyl-*p*-benzoquinoneimine; NKK, 4-methylnitrosamino)-1-(3-pyridyl)-1-butanone.

^aDisulfiram metabolite generated in liver.

Figure 8.8 Mechanism of reactive metabolite-induced toxicity. (See color insert.)

Table 8.6 summarizes the nature of toxicity shown by different xenobiotics in extra-hepatic organs, with indications on the mechanisms involved.

Since the GIT is rich in different DMEs, orally administrated drugs can be metabolized, which may lead to the generation of reactive metabolites and subsequent toxicity. For example, acrylonitrile, a dietary carcinogen, is metabolized to form reactive epoxide in intestine by CYP2E1 and to a lesser extent by CYP2B1. This metabolite is responsible for the generation of toxicity in the intestine by three pathways: (i) direct binding with nucleophilic moieties, such as DNA and proteins, and the release of cyanide (CN^-); (ii) hydrolysis followed by the release of CN^- ; and (iii) interaction with sulfhydryl compounds (GSH and/or *N*-acetylcysteine) with associated release of CN^- (Fig. 8.9). This conversion of acrylonitrile to CN^- group is enhanced by phenobarbital, BNF, 4-methylpyrazole, or ethanol [547].

Like GIT, the lung is also susceptible to toxicity because of the formation of reactive metabolites. Lungs are directly exposed to air, so these come in direct contact with pollutants. Owing to abundant oxygen in lung, environmental contaminants have the potential to undergo redox reactions, resulting in the formation of oxygen superoxide radicals that can result in toxicity to the pulmonary system [580]. The lung is additionally exposed to drugs and xenobiotics through extensive cardiac output that circulates through them. Xenobiotics, such as 4-ipomeanol and 3-methylindole, are metabolized in different tissues and subsequently transported to lung through blood

TABLE 8.6 Toxic Events Attributed to Different Xenobiotics in Extrahepatic organs, Including the Mechanisms Involved

Organ	Xenobiotics	Enzyme	Reactive Metabolite	Mechanism	Outcome	References
Gastrointestinal tract	Acrylonitrile	CYP2E1 and CYP2B1	Epoxide intermediate	Can bind directly to nucleophilic moieties or release reactive CN ⁻	Carcinogenicity	547
	5-Fluorouracil	—	—	—	Apoptosis or cell cycle arrest in intestinal epithelial cells	548
Gastrointestinal tract + pulmonary system	Benzo(α)pyrene	CYP1A1, CYP1B1, CYP2C, CYP3A4, AKR1A1 AKR1C1-1 C4, and EH	Epoxide, quinone metabolites	Electrophile and free radical generation	Form covalent adducts with DNA, resulting in mutation of <i>p53</i> gene, leading to lung carcinogenicity	7,373,502,503, 549–551
	Aromatic and heterocyclic amines	CYP1A2, CYP1A1, CYP1B1, NAT1, NAT2, SULT1A1, SULT1A2, and SULT1A3	Nitrenium ion	N-Hydroxylation, sulfonation metabolism	DNA adduct formation, resulting into carcinogenicity	55,373,552
Pulmonary system	Naphthalene	CYP2F2	1 <i>R</i> , 2 <i>S</i> - to 1 <i>S</i> , 2 <i>R</i> -epoxide metabolite	Oxidative metabolism	GSH depletion, adduct formation cellular proteins, nonciliated airway epithelial cell injury	553–556

(continued overleaf)

TABLE 8.6 (continued)

Organ	Xenobiotics	Enzyme	Reactive Metabolite	Mechanism	Outcome	References
	4-Ipomeanol	CYP1A2, CYP2B7, CYP3A3, CYP3A4, and CYP2F1	Epoxide intermediate	Oxidative metabolism	Edema, congestion, and hemorrhage	513,557,558
	3-Methylfuran	CYP	—	—	Bronchiolar alkylation and necrosis of nonciliated bronchiolar cells (Clara cells)	559
	Bromobenzene	CYP	Bromobenzene-3,4-oxide	—	GSH depletion, cellular damage, and lipid peroxidation	560–562
	3-Methylindole	CYP1A1, CYP2A13, CYP2F1, and CYP4B1	Epoxides and free radical intermediates	Oxidative metabolism	Covalent binding to proteins and nucleic acids or stimulation of lipid peroxidation leads to alveolar type 1 and nonciliated bronchiolar epithelial cells injury	504,563,564
	Butylated hydroxy-toluene	CYP2B	6- <i>Tert</i> -butyl-2-[2'-(2'-hydroxy methyl)-propyl]-4-methylphenol, 4-hydroperoxy-4-methyl-2,6-di- <i>tert</i> -butyl-2,5-cyclohexadienone	Hydroxylation metabolism	Lung damage and elevated risk of lung tumor development	565–567
	Carbon tetrachloride	CYP	—	—	Clara and type II cell damage	561

1,1-Dichloro-ethylene	CYP2E1 and CYP2F2	2,2-Dichloroacetaldehyde, 1,1-dichloroethylene-epoxide	Oxidative metabolism	Clara cell toxicity	568
Styrene	CYP2E1 and CYP2F2	7,8-Styrene oxide	—	Tumor, Clara, and terminal bronchiole cell toxicity	569
<i>p</i> -Xylene	CYP and ADH	<i>p</i> -Methylbenzylalcohol, <i>p</i> -methylbenzaldehyde	—	Cell destruction	570,571
α -Naphthylthiourea	CYP	α -Naphthylurea, atomic sulfur	—	Atomic sulfur formed in this reaction covalently binds to macromolecules, pulmonary edema	572,573
Monocrotaline (pyrrolizidine alkaloids)	—	Ehrlich reactive (E+) metabolite	Activated in the liver to an Ehrlich reactive metabolite that is transported to the lung	Swelling of pulmonary capillary endothelial cells, thrombosis, and lesions of the arterial media	574,575
Bleomycin	Mixed-function oxidase	—	—	Increased lung collagen synthesis and deposition finally leads to pulmonary fibrosis	576

(continued overleaf)

TABLE 8.6 (continued)

Organ	Xenobiotics	Enzyme	Reactive Metabolite	Mechanism	Outcome	References
	Mitomycin C	NADPH:cytochrome <i>c</i> reductase and DT-diaphorase	Semiquinone radical and hydroquinone intermediate	Metabolism takes place under anaerobic conditions	Cellular toxicity	577
	Cyclophosphamide	—	4-Hydroxycyclophosphamide, acrolein and phosphoramidate mustard	—	Alterations in mixed-function oxidase activity, glutathione content, and lipid peroxidation	435,578
	Paraquat	NADPH cytochrome <i>c</i> reductase	Paraquat free radicals	Elevates superoxide levels by cyclic redox mechanism	Covalent adducts with DNA and proteins or form lipid peroxide and can lead to the damage of type II pneumocytes	549,579,580
	Nitrofurantoin	Not specified	Nitro free radical	Electron reduction	Covalent adducts with proteins or spontaneously reacts with oxygen molecules to yield reduced oxygen	579,580
	NKK	CYP2A6, CYP2A13, and CYP2B6	4-Hydroxy-1-(3-pyridyl)-1-butanone, 4-oxo-1-(3-pyridyl)-1-butanone, methyldiazohydroxide	α -Hydroxylation of methyl or methylene carbon	Forms adduct with DNA can lead to carcinogenicity	20,581,582

Urinary system	Aflatoxin B1	CYP2A13	Epoxide intermediate	Oxidative metabolism	Binds with DNA, RNA, proteins, and potentiates <i>p53</i> gene mutation and inactivation, resulting in lung cancer	7,505,583
	<i>N</i> -Nitrosamines	CYP2E1	—	—	Cancer of lungs, nasal cavity, liver, breast and esophagus	170
	Parathion	CYP reductase and amine oxidase	Paraoxon, diethyl hydrogen phosphorothionate, diethyl hydrogen phosphate	—	Respiratory edema, respiratory failure, and cancer development	561,584,585
	Skatole	CYP2F1	—	Oxidative metabolism	Necrosis	180
	Hexafluoropropene	GSH	<i>S</i> -(1,1,2,3,3,3-Hexafluoropropyl) glutathione	Conjugation	Undergoes further metabolism by γ -GT	586
	<i>S</i> -(1,1,2,3,3,3-hexafluoropropyl) glutathione	γ -GT	Cysteine <i>S</i> -conjugate	Glutamyl removal	Undergoes further metabolism by β -lyase	586
	Cysteine <i>S</i> -conjugate	β - Lyase	Thionoacyl fluoride	Lysis	Nephrotoxicity	586
	Chloroform	CYP2E1	Phosgene	Oxidative metabolism	Nephrotoxicity	587–589
	Cephaloridine	Mixed-function oxidase	Epoxide intermediate	Oxidative metabolism	Nephrotoxicity	590,591

(continued overleaf)

TABLE 8.6 (continued)

Organ	Xenobiotics	Enzyme	Reactive Metabolite	Mechanism	Outcome	References
Central nervous system	Aristocholic acid	CYP1A1	7-(Deoxyadenosin- <i>N</i> -6-yl) aristolactam I, 7-(deoxyguanosin- <i>N</i> -2-yl) aristolactam I, and 7-(deoxyadenosin- <i>N</i> -6-yl) aristolactam II	—	Urothelial cancer	8
	Bromobenzene	CYP	—	—	GSH depletion, cellular damage, and lipid peroxidation	562
	Parathion	CYP reductase	Paraoxon, diethyl hydrogen phosphorothionate, diethyl hydrogen phosphate	—	Nephrotoxicity	585
	Methoxyflurane	CYP2E1, CYP2A6, and CYP3A	—	Glutathione and cysteine conjugate	Nephrotoxicity	592
	Benzidine	CYP1A2	—	Oxidative metabolism	Urinary bladder cancer	180

circulation, where these can result in toxicities due to covalent adduct formation [580]. Similarly, metabolic activation in lung and the formation of covalent adducts with nucleophilic species with resultant pulmonary toxicity is reported for many other xenobiotics [168]. Of special interest with respect to toxicity in both GIT and lungs are PAHs (food and air contaminants) that have the potential to result in carcinogenicity [7,373,502,503,549–551]. Inhaled air and cigarette smoke are major reasons for the exposure of lung to PAHs, while GIT is exposed to these as food contaminants. In both organs, CYP1A1, CYP1B1, EH, CYP2C, CYP3A4, aldo-keto reductase 1A1 (AKR1A1), AKR1C1, AKR1C2, AKR1C3, and AKR1C4 are responsible for the metabolic activation of PAHs, which actuate the formation of epoxide and quinone reactive metabolites, as shown in Fig. 8.10. These metabolites show genotoxicity by forming covalent adducts with DNA, resulting in mutation of *p53* gene and hence, the development of malignancy.

Similarly, the kidneys are also susceptible to drug toxicity. For example, kidneys receive 25% of the cardiac output, although these represent only 1% of the body mass, leading to high exposure to xenobiotics. The bioactivation of xenobiotics in kidney is mediated by local DMEs, and the ability of the kidneys to concentrate xenobiotics in the tubular fluid/tubular cells can result in renal toxicities with chronic administration. Examples of xenobiotics that induce nephrotoxicity are chloroform, cephaloridine, aristocholic acid (ARA), hexafluoropropene (HFP), and methoxyflurane [8,586–591,600,601].

Aromatic and heterocyclic amines present in cigarette smoke may cause tumors in GIT, lungs, kidneys, and urinary bladder after NAT-dependent modulation. NAT1 plays role in the activation of aromatic amines through O-acetylation of *N*-hydroxyl aromatic amines (generated after metabolized by CYP1A1, CYP1A2, and CYP1B1), whereas NAT2 is associated with N-acetylation, leading to deactivation of aromatic amines. These activation and deactivation reactions are responsible for the carcinogenic effects on GIT, lungs, and urinary bladder [55,373,552,602,603], as shown in Fig. 8.11.

N-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), an impurity present in a fast acting opioid analgesic, meperidine, has been reported to be neurotoxic. In brain, MPTP is metabolized by MAO-B to generate 1-methyl-4-phenyl 2,3-dihydropyridinium ion (MPDP⁺). This is finally converted into *N*-methyl-4-phenylpyridinium ion (MPP⁺), as shown in Fig. 8.12. MPP⁺ inhibits mitochondrial respiration in the nigrostriatal neurons and leads to an energy-deficient condition and degeneration of the latter, resulting in Parkinson's disease [593]. In this type of toxicity, MAO inhibitors and antioxidants have the potential to prevent oxidation of MPTP⁺ to MPDP⁺/MPP⁺ in mitochondria and thus act as neuroprotective agents [604].

Figure 8.11 Bioactivation pathway of aromatic and heterocyclic amines depicting inception of lung/GIT/urinary bladder cancer [373].

8.6.3 Interactions in Extrahepatic Organs

Pharmacokinetic or pharmacodynamic properties of drugs may be altered in the presence of coadministered drugs, food, and environmental toxicants. While pharmacokinetic interactions are due to changes in absorption, distribution, metabolism, or excretion of drugs, the pharmacodynamic interactions are primarily attributed to changes at the target site (synergism or antagonism). A significant proportion of drug interactions occur owing to inhibition/induction of DMEs, not only in liver but also in extrahepatic organs. For example, oral administration of rifampicin results in significant induction of CYP3A4, CYP2C8, and CYP2C9 in GIT, which leads to enhancement of the metabolism and decrease in the bioavailability of

Figure 8.12 Generation of reactive *N*-methyl-4-phenylpyridinium ion (MPP⁺) in the brain from *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP).

the coadministered CYP substrate drugs [605]. Rifampicin increases apparent oral clearance of CYP3A4 substrates, for example, *S*-verapamil, cyclosporine, and midazolam, and accordingly decreases their bioavailability [605]. Symptoms of methadone withdrawal were observed in drug addicts taking rifampicin simultaneously for the treatment of tuberculosis [606]. Similarly, St. John's wort, a herb, has been reported to interact with a number of drugs by inducing CYP3A4 in the human intestine. CYP inhibitors, such as ketoconazole, erythromycin, clarithromycin, grape fruit juice, and troleandomycin, lead to dose-dependent toxicity of CYP3A4 substrates by increasing their bioavailability [154,458,459,607]. A summary of published drug–drug interactions in extrahepatic organs are described in Table 8.7.

8.7 CONCLUSIONS

Along with the liver, DMEs are expressed in extrahepatic organs, and their levels are significantly influenced by changes in food habits, pathophysiological conditions, exposure to environmental pollutants, smoking, and so on. These enzymes are responsible for the biotransformation of xenobiotics and convert them into relatively hydrophilic metabolites that can be cleared from the body. The high allelic variation in extrahepatic DMEs contributes to the generation of diseases observed in certain populations. Biotransformation reactions involving extrahepatic DMEs are involved in the generation of reactive metabolites, such as epoxide and quinone, which lead to organ toxicity by either directly binding with nucleophilic molecules in the cells or inducing cellular stress. The involvement of extrahepatic DMEs in the metabolism of drugs influence their bioavailability when administered by oral, inhalational, and transdermal route.

Although extensive work has already been done to explore DMEs in various extrahepatic organs and characterize their role, there are still some unanswered aspects. The total contribution of extrahepatic DMEs on the bioavailability of drugs given by non-parenteral route and in drug–drug interactions and organ toxicity are not completely understood. The relative ratio of contribution of extrahepatic xenobiotic transporters and DMEs to bioavailability and clearance is also not understood. Finally, it is not

TABLE 8.7 Drug Interactions in Extrahepatic Organs and Potential Risk Factors

Organ	Substrates	DME	Interacting Agent	Cause of DDI	Potential Risk	References
Gastrointestinal tract	Cyclosporine	CYP3A4	Grape fruit juice	Enzyme inhibition	Nephrotoxicity, hypertension, cerebral toxicity	607
			Erythromycin	Enzyme inhibition	Nephrotoxicity, hypertension, cerebral toxicity	459
			Ketoconazole	Enzyme inhibition	Nephrotoxicity, hypertension, cerebral toxicity	154
			St. John's wort	Enzyme induction	Nephrotoxicity, hypertension, cerebral toxicity	608
	Saquinavir	CYP3A4	Garlic	Enzyme induction	Reduced therapeutic efficacy due to the lowering of $C_{\max}$	609,610
	Ritonavir	CYP3A4	Garlic	Enzyme induction	Reduced therapeutic efficacy due to the lowering of $C_{\max}$	609
	Tacrolimus Midazolam	CYP3A4	Ketoconazole	Enzyme inhibition	Neurotoxic, nephrotoxicity	611,612
		CYP3A	Clarithromycin	Enzyme inhibition	Increased CNS depression	613
			Erythromycin	Enzyme inhibition	Increased CNS depression	614
			St. John's wort	Enzyme induction	Reduced therapeutic efficacy due to the lowering of $C_{\max}$	615
	Carvediol	CYP3A4	Grape fruit juice	Enzyme inhibition	Increased CNS depression	616
			Grape fruit juice	Enzyme inhibition	Lethal effect in congestive heart failure patient	610
	Felodipine	CYP3A	Grape fruit juice	Enzyme inhibition	Hypotension, ankle edema	617–619
	Indinavir	CYP3A	Ketoconazole	Enzyme inhibition	Nephrotoxicity	446,620
	Fentanyl	CYP3A	Troleandomycin	Enzyme inhibition	Reduced cerebral blood flow	458,621
	Alfentanil	CYP3A	Erythromycin	Enzyme inhibition	Vasodilation and hypotension	458
			Troleandomycin	Enzyme inhibition	Vasodilation and hypotension	458

	Sildenafil	CYP3A4	Grape fruit juice	Enzyme inhibition	Hypotension, decrease in arterial pressure	607,622
	Simvastatin	CYP3A	Grape fruit juice	Enzyme inhibition	Rhabdomyolysis, acute renal failure	623
	Verapamil	CYP3A4	Rifampicin	Enzyme induction	Reduce efficacy	605
			Grape fruit juice	Enzyme inhibition	Cardiovascular side effects	605,624
	Halofantrine	CYP3A4	Ketoconazole	Enzyme inhibition	Cardiac arrhythmia	625,626
	5-Fluorouracil	All DMEs	Nifedipine	Enzyme inhibition	Dose-dependent cardiac toxicity	627,628
	Finasteride	CYP3A4	Ketoconazole	Enzyme inhibition	—	629
	Tamoxifen	CYP2D, 3A1/2	Ondansetron	Enzyme inhibition	Pharmacokinetic interaction	630
	Hormone replacement therapy	CYP3A4	Licorice	Enzyme induction	Reduction in efficacy	610
Pulmonary system	Amiodarone	CYP1A1	PAHs	Enzyme induction	Pulmonary fibrosis	631
	Hormonal contraceptives	CYP1A1/2	PAHs	Enzyme induction	Increases chances of conceiving	632
	Inhaled corticosteroids	CYP1A1/2	PAHs	Enzyme induction	Aggravate of asthma	632
Urinary system	Diltiazem	CYP3A5	Tacrolimus	Enzyme inhibition	Nephrotoxicity	631

(continued overleaf)

clear whether extrahepatic metabolism provides beneficial effects by neutralizing carcinogens to which different organs of the body are exposed or if these are involved in detrimental effects by metabolic activation of procarcinogens. Continued research in this broad area will provide more answers and aid in the predictions of clinical end points.

9.1 SUMMARY

Mass balance studies play an important role in the development of new drugs. These studies give in-depth understanding of absorption, bioavailability, and routes (renal, biliary, hepatic, or gastrointestinal) and extent of excretion, metabolite profiling, metabolic pathways, and clearance mechanisms of a drug. In this chapter, fundamental scientific considerations for the successful design, conduct, and interpretation of conventional, basic mass balance and more comprehensive absorption, distribution, metabolism, and excretion (ADME) studies are reviewed and applied, practical case examples are provided.

9.2 INTRODUCTION

Before first-in-human (FIH) studies with a new drug candidate, preclinical studies need to be conducted to fulfill regulatory requirements or to facilitate regulatory approval [1]. In the United States, investigational new drug (IND) applications with the Food and Drug Administration (FDA) may include IND enabling studies, such as (i) *in vitro* and *in vivo* pharmacology studies for intended use; (ii) toxicology studies supporting the starting dose and duration of an FIH study (such as single or multiple-dose studies in one rodent and nonrodent species with toxicokinetics, genotoxicity battery, and safety pharmacology battery); (iii) single-dose pharmacokinetics (PKs) in one rodent and nonrodent species; (iv) *in vitro* plasma protein binding in relevant species; and (v) *in vitro* cross species metabolism study in relevant species [2]. While not mandatory for IND submissions, comprehensive preclinical ADME studies, including biotransformation or metabolite profiling, conventional mass balance, or tissue distribution by quantitative whole-body autoradiography (QWBA) [3] can make a submission package more compelling for progression toward phase I clinical studies. Typically, preclinical ADME together with mass balance studies are recommended before conducting human ADME and mass balance studies [4,5], which are generally initiated after the successful synthesis of the radiolabeled drug. An example of the typical timings for conducting mass balance studies during the drug development process is shown in Fig. 9.1. For pre-clinical ADME species, the selection of doses is often based on pre-existing toxicity information and targeted therapeutic doses. For human ADME studies, which include the evaluation of mass balance, a relevant dose in the anticipated therapeutic range is typically chosen. Conventional mass balance studies only allow the calculation of mass recovery and PK parameters of the radiolabeled drug by quantification of the radioactivity present in excreta such as urine, feces, or bile. Nowadays, these mass balance studies are often conducted as part of more comprehensive ADME studies, where additional information is obtained, including (i) PK properties of the drug and its metabolite(s) in blood or plasma; (ii) absorption estimates via plasma/blood data, urinary data, or fecal data; (iii) elimination pathways and drug metabolism; and (iv) total drug exposure and its metabolites in different organs and tissues at different time intervals.

Figure 9.1 Representation of the timings for the conduct of animal and human mass balance studies parallelly in the drug development process.

9.3 PURPOSE AND SPECIFIC AIMS

The purpose of mass balance studies along with ADME studies [6,7] can be summarized as follows:

1. To determine absorption of drug after extravascular administration.
2. To identify excretory pathways and recovery of drug-related radioactivity (usually urine and feces) in early stages of drug development.
3. To characterize the PKs of the intact parent drug and its metabolites as well as their contribution toward pharmacology/toxicology.
4. To determine clearance mechanisms, including metabolic and excretory fates and understand potential contributors of intersubject variability associated with drug–drug interactions (DDIs), supported by the identities of drug-related material in excreta.
5. To determine the organs/tissues distribution in preclinical species, which can be a cause for incomplete recovery of radioactivity in excreta, caused by significant retention in specific organs or tissues.
6. To provide all necessary information from preclinical studies in terms of design and potential risks, including dosimetry of radiation to support mandatory human mass balance studies.
7. To guide the use and choice of preclinical species in the toxicity studies based on the metabolite profiles.

Conventional mass balance studies in their simplest form allow the determination of excretory pathways of drug and its metabolites by determining the cumulative radioactivity recovered in excreta after an extended collection period, relative to the dosed amount of radiolabeled drug, most commonly via the oral (p.o.) or intravenous (i.v.) routes [7]. To study the mass recovery, the radiolabeled drug is typically administered to facilitate the identification and quantification of parent drug as well as its metabolites in different biological matrices. The data obtained from these studies are multifarious, as when a drug is administered to animals or humans, it undergoes a series of events such as absorption, distribution, and metabolism, which govern the drugs systemic exposure, and its pharmacological response [8] or pharmacodynamic effect, as well as its excretion routes [7,9]. For investigational drug candidates, ADME and mass balance properties can be crucial determinants in the selection process, leading to optimized clinical outcomes for drug candidates [10]. Essential elements for design and conduct of mass balance study have been described previously by Tse *et al.* [11] and Beumer *et al.* [4]. This chapter summarizes detailed factors to be considered when designing and conducting various types of ADME and mass balance studies, including how to (i) choose of the best dose, dosing route, in a suitable preclinical species; (ii) clearly identify major excretory pathways; (iii) identify and troubleshoot causes of low drug recovery; (iv) determine PK and ADME properties using total radioactivity or intact parent drug data; and (v) conduct dosimetric calculation to extrapolate from animal to human. A case example in rats is given to provide details on the conduct of a mass balance studies. Moreover, the purpose and conduct of human mass balance studies are reviewed.

9.4 EXPERIMENTAL DESIGN OF PRECLINICAL MASS BALANCE STUDIES

To identify metabolic routes of a drug candidate in early development stages, *in vitro* studies provide a basic direction for the preclinical studies in animals [12,13]. A carefully designed mass balance study, which includes metabolite identification in plasma, urine, bile, and feces can further aid in the identification of excretory and metabolic routes. Common challenges related for the successful study conduct include proper dose selection, bioanalytical factors, suitable formulations, and potential toxicities. Details for experimental design, along with study result interpretation are outlined. To aid in clarity, a preclinical rodent study can be divided into six groups. Two groups, one each for p.o. and i.v. administration, are used for the interpretation of mass balance data, absorption, and PK parameters such as fraction absorbed (F_{abs}), area under the time–concentration curve (AUC), and clearance (CL). Two additional groups, one each for p.o. and i.v. administration, are dedicated for biotransformation studies and metabolic profiling. The metabolite profiles from the i.v. dosed group, when compare to the p.o. dosed group, can provide the information on whether the drug is subjected to the first-pass metabolism in gastrointestinal tract. The remaining two groups, each separately for p.o. and i.v. dose administration, are used for biliary excretion studies, in which one continuous loop nonvascular catheter is surgically implanted. The i.v. dose in bile-duct cannulated (BDC) rats can further distinguish biliary excretion from the secretion of drug from the gastrointestinal tract, if any. Blood, urine, feces, and bile samples are collected at the designated time following the dosing. The carcasses are also collected for potential analysis in cases where the total recovery in excreta is low.

From the group where the mass balance is studied, a mass balance recovery <80% can possibly lead to challenges from regulatory agencies, as the mass balance study might not provide a complete picture of ADME parameters. Some publications put the recovery cutoff at 90% [4] and 85–95% or above as the boundary for the success or failure of a mass balance study [14]. Understanding the causes for incomplete mass recovery is typically required but can be challenging at the early development stage. Sometimes, incorporation of QWBA data for the analysis of tissues and organs distribution of radioactivity in mass balance studies can be used to understand the incomplete mass balance recoveries.

9.4.1 Choice of Preclinical Species

For ADME studies as a part of nonclinical safety testing, two animal species, one rodent (rat or mouse) and one nonrodent (dog or monkey), are usually chosen [15,16]. Rodents are the most common and suitable choice of species for preclinical mass balance studies. For species selection, the difference in strain, age, sex, genetic modification, and body weight can have a significant impact on the studies [4] and must be considered. More importantly, the interpretations of any ADME studies often require consistency for results comparisons between studies; thus, it is recommended to use the same rodent strain with a close match of age and weight as used in the toxicity studies. Male animals are normally used for the ADME studies unless the drug is developed for use in female patients only. Female animals may be used if there are significant differences in toxicokinetics parameters between genders are observed and *in-vitro* metabolism cannot explain the results. If the drug is being developed for an

IND application with Japanese regulatory agencies, studies in both male and female animals may need to be conducted. Disposition studies may be conducted in other species such as rabbits, which is used for reproduction or teratogenicity studies, or in the mouse, which is used for carcinogenicity studies. Dogs and monkeys are normally used as nonnative animals. Special studies in female rats such as placenta and milk transfer studies are required and are usually conducted at late stage of the drug development. Before the actual dose administration, animals are usually housed for at least 14 days for quarantining or conditioning [2] with controlled conditions (in a room with controlled temperature ranges typically at $72 \pm 2^\circ\text{F}$), and a humidity range of $50 \pm 15\%$, and dietary conditions (fed or fasted) in accordance with Guidance for the Care and Use of Laboratory Animals. In this chapter, the focus is on the mass balance studies in rats in order to cover fundamental aspects of mass balance studies (including recovery from different matrices, e.g., excreta, tissue dissection, QWBA, carcass, and CO_2 exhalation) because rats are the most common and suitable choice of species. A schematic representation of the rat model used in a typical ADME study, including common routes of administration, absorption, metabolism, and excretion from different matrices, is illustrated in Fig. 9.2. A summary of animals commonly used for

Figure 9.2 Schematic representations of various dosing, absorption, metabolism, and excretion routes. The most common dosing routes for mass balance studies are oral (p.o.) and intravenous (i.v.) administration. Urine and feces are separately collected after excretion. For biliary excretion studies, the bile duct that drains the bile from the liver to the upper part of intestine, usually duodenum, can be cannulated to collect bile. “D” represents p.o. or i.v. dosing routes, “A” represents various absorption sites, “M” represents metabolism sites, and “E” represents various excretion routes. *Urinary excretion site. **Fecal excretion site. ***Biliary excretion site. *Source:* The figure was drawn by Nicole Heimbach.

TABLE 9.1 Factors in the Choice of Animals, Dose, and Formulations for Mass Balance or ADME Studies with Rationale and Comments

Factors	Design	Rationale and Comments
Dose levels	<i>Intravenous dose:</i> usually 20–100% of oral dose (based on bioavailability and solubility) <i>Oral dose:</i> usually in the range of anticipated NOAEL dose studies	Ideally target similar exposure between oral and intravenous doses Support the toxicity study
Dose volume	<i>Intravenous:</i> ≤ 2 mL/kg <i>Oral:</i> ≤ 10 mL/kg for rodents and ≤ 5 mL/kg for large animals; ideally the same as planned for toxicity studies	Ethical reasons and animal welfare considerations
Formulation	Ideally same formulation as in toxicity studies	As in toxicity studies After administration, an aliquot of formulation is frozen as a reference check in metabolic studies
Dose regimen	Single dose	—
Species ^a /weight (kg)	Dose for [¹⁴ C]-labeled drug ^b (μ Ci/kg)	—
Mouse (0.025–0.040)	100–300	For higher species, avoid high radioactive doses as animals are returned to colony
Rat (0.15–0.30)	100–300	—
Dog (8–13)	20–30	—
Monkey (2.5–4)	20–30	—
Rabbit (2–4)	30–50	—
Subject number	$N = 3$ for each route ^c	—
Feeding	Should be same as in toxicity studies	
Housing	Individually in metabolism or housing cages	

Abbreviation: NOAEL, no observed adverse effect level.

^aMouse and rat studies support the carcinogenicity study; rat, dog, and monkey studies support the general toxicity study; rat and rabbit studies support the teratogenicity study.

^bFor [³H]-labeled drug, ≤ 500 μ Ci/kg for rodents and ≤ 100 μ Ci/kg for large animal.

^cIn mice, urine and feces may be pooled per time point. For PK and metabolite profiling in mouse plasma, due to small sample size, two to three animals per time point for each route may be used. In rats, additional three animals each will be needed for plasma metabolite identification and biliary excretion. In large animal, for intravenous dosing studies, often two animals are used due to more sample volume available and lower experimental variability compared to oral dosing.

the mass balance studies is listed in Table 9.1. All studies are designed to maximize quantitative aspects of the drug molecule, while minimizing radioactivity exposure.

9.4.2 Choice of Dose, Route of Administration, and Formulation

In mass balance studies, as most compounds undergo metabolic transformation before excretion, a radioisotopically labeled compound is commonly used so that both unchanged compound (parent drug) and its metabolites in different biological matrices can be accurately quantified. The total dose of the compound (radiolabeled and unlabeled) under investigation needs to be pharmacologically relevant and

comparable to toxicological doses [4]. Most of the time, the radiolabeled compound is diluted with nonradiolabeled compound to achieve the total targeted dose to be administered to the subjects for both preclinical (animal) and clinical (human) studies as the required radioactivity is typically only a trace amount. Moreover, the radiolabeled dose depends on the specific objectives of the study and sensitivity of the analytical method. The specific activity of the radioactivity in the dose must be chosen carefully, as the nonradiolabeled dose determines the PKs of the parent drug and mass balance studies for clinical practice, while the radiolabeled dose influences both the radioactive exposure in the animal/human and the analytical limits of quantification. For human studies, the route of administration preferred is the same as the intended route for the drug's clinical use, as the formation of metabolites and extent of metabolism may differ with the route of administration [7]. The selection of the radioactive dose amount is based on the balance between the radioactive exposure limits as outlined in 21 CFR 361.1 [1], other local radiation guidelines and regulations, and the safety/efficacy profiles of the drug molecule. The purity of the radioactive tracer used for the study plays an important role as impurities may result in different PK characteristics, metabolite profiles, and may result in toxicity concerns. The radioactivity purity must be >98% for mass balance studies unless there is a limit in purification technique. Various factors related to the choice of doses and formulations have been summarized in Table 9.1.

For p.o. administration, solutions, suspensions, or loose filled capsules prepared in certified labs are generally used for mass balance studies. A dosing vehicle also used in the toxicity studies is the preferred choice for preclinical mass balance studies. Solution formulations are a common choice with minimal difference in the physical properties (particle size) between radiolabeled and nonlabeled drug substance. For suspension or capsule formulations, care must be taken to ensure uniform distribution of radioactivity within the dose [7]. A premixed blend prepared by dissolving the radiolabeled and unlabeled drugs in appropriate solvent(s) followed by removal of solvent(s) can eliminate uniformity issues. Preparing the radiolabeled dosage form with commercially available large-scale manufacturing equipments will increase the risk of unnecessary radioactive contamination and is generally not preferred.

9.4.3 Choice of Matrices

The quantitative analysis of all mass balance studies is based on the cumulative amount of radioactivity collected in a given matrix at the given collection interval. Usually, blood, urine, and feces are routinely collected during a typical mass balance study. In order to understand the mechanism of clearance and potentially incomplete radioactivity recovery, more information can be obtained by sampling additional matrices, including bile, tissues, organs, carcass, and expired air [17]. The sample collection of blood and excreta begins before drug administration and continues until maximum recovery of radioactivity is achieved. The radioactivity of blood, plasma, urine, bile, feces, and cage wash samples is determined by liquid scintillation counting, while the parent drug is usually determined using the HPLC or liquid chromatography-tandem-mass spectrometry (LC-MS/MS) methods. The sample collection can be stopped when <1% of administered radioactivity is excreted for two consecutive days, as prolonged collection will not substantially increase recovery [4]. Moreover, the sample collection

time should also be practical for PK parameter calculations. The sample collection for different matrices is discussed in the following sections.

9.4.3.1 Blood and Plasma. Blood and plasma samples are generally used for the PK studies of both nonlabeled and radiolabeled compound. The choice of blood and plasma sample selection should be based on the blood-to-plasma distribution ratio, due to different PK behavior of unchanged drug and its corresponding metabolites in blood versus plasma. In the case of i.v. dosing, an early sample is imperative to determine the maximum plasma concentration (C_0). Thereafter, samples need to be collected at appropriate intervals in order to characterize the distribution and elimination phase separately. In the case of p.o. administered drugs, samples are frequently collected around the expected time of maximum plasma concentration ($C_{\max}$). When designing the time points to take a sample, the volume of samples collected should be sufficient for at least one bioanalytical measurement. In the example of the rat ($n = 3$), blood (200 μL) can typically be collected at 0.083 (i.v. only), 0.25, 0.5, 1, 2, 4, 8, 12, 24, 48, 72, 96, and 168 h post dose. The blood samples are added preheparinized tubes in cooled (4°C) sample collecting carousals using automatic sample collecting systems such as a Culex[®] system. Saline (200 μL) is automatically injected after each sample is collected to clear the cannula and replace the volume of blood samples. The blood samples are further spun to collect the plasma at 4°C . The total blood volume collected should not exceed 1% of the animal's body weight. For metabolite profiling, 250 μL of blood samples are collected from each of three rats at each time point up to 48 h using the same procedures mentioned above. The samples are pooled, and then spun to separate the plasma. The total radioactivity of radiolabeled drugs can be measured using the liquid scintillation counting (LSC) method. The concentration of nonlabeled or parent drug in blood or plasma can be measured using different chromatographic instruments (e.g., HPLC and GC), mass spectrometers (e.g., LC-MS/MS), or other suitable analytical methods (e.g., ELISA). Sample pretreatment methods for the determination of radioactivity differ for blood and plasma. The plasma samples are transparent and therefore can be directly measured after mixing with liquid scintillation fluid for the quantification of radioactivity using LSC. Generally, decolorization is required for blood samples to reduce color quenching. This is achieved using a tissue solubilizer and oxidizer (such as 30% hydrogen peroxide). EDTA (50 μL of 100 mM) as an antifoaming agent can be added to the solubilized sample before addition of hydrogen peroxide. Alternatively, the combusting method can be used to collect $^{14}\text{CO}_2$ or $^3\text{H}_2\text{O}$ derived from the samples. A detailed list of various parameters needed to be considered in designing and handling of blood and plasma matrices following with rationale and comments is provided in Table 9.2.

If a tritium radiolabeled compound is used, then the samples to be analyzed for the radioactivity should be dried before analysis, as $^3\text{H}_2\text{O}$ has a long half-life and can interfere with the radioactivity of drug-related substances. Since the dried sample is hard to redissolve in the liquid scintillation cocktail, it is recommended that the dried sample be dissolved in solubilizer first, if the solubilization method instead of the combusting method is used.

9.4.3.2 Excreta and Cage Wash. Urine and feces are typically collected from each PK study groups at defined time intervals: pre dose, 0–24, 24–48, 48–72, 72–96, and 96–168 h post dose. Urine is a liquid matrix that can be collected separately from the

TABLE 9.2 List of Various Parameters Needed to be Considered in Designing and Handling of Blood, Plasma, and Excreta Matrices, with Rationale and Comments

Sample Collection	Design	Rationale and Comments
<i>Blood samples</i>		
Blood/plasma collection time points	<i>Intravenous and oral dose:</i> pre dose, 6–8 points on day 1. Then sampling at desired time points up to seven days	Ideal for PK calculations even if terminal half-life is long
Volume of blood sample	≤0.25 mL from rodents; 2 mL from rabbits, dogs, and monkey; 10 mL from human	Allows analytical measurements for PK, including radioassay and metabolic profiling
Number of measurements	One per time point of each individual in ADME studies	Small volume Pooled samples per time point may be analyzed if limited sample available
<i>Excreta samples</i>		
Urine, feces, and cage wash collection	Separate collection of urine and feces on ice (no cooling after 96 h); modified metabolic cage preferred	Mass balance and metabolite profiling (avoid degradation) Pooled collection per time point for urine and feces may be needed for mice
Time intervals	Daily up to 168 h post dose; Fixed time interval (0–24, 24–48, 48–72, 72–96, 96–168 h) or pooled for mass balance studies	To determine mass balance, metabolic, and excretory pathways
Cage wash	Extensive cage wash after last day, separate workup	Increase recovery and safety aspects (clean cages to be returned to storage)
Number of radioactivity measurements	<i>Urine:</i> One per time interval and for each species under study; <i>Feces:</i> Two per time interval and for each species under study; <i>Cage wash:</i> One per animal	Repeat if mean difference is >10% and total content >1% of dose

feces with a modification of a metabolic cage as represented in Fig. 9.3 for rodents. The urine samples are collected in defined time intervals in order to calculate the total excretion of the compound and its metabolites. The urine collection containers should be placed on ice bath or frozen conditions to reduce possible chemical degradation. The total volume and pH of the urine sample should be accurately measured. After collection, urine samples are quantitatively analyzed for radiolabeled drug, unlabeled drug, and/or their metabolites. The percentage recovery of radioactivity in urine is calculated from the ratio of concentration and volume recovered in the urine to the total concentration and volume dosed, where concentration is given in disintegrations per minutes (DPM) per milliliter and is represented by Equation 9.1:

% Recovery in urine

$$= \frac{\text{Volume recovered in urine (mL)} \times \text{Urine concentration (DPM/mL)}}{\text{Volume dosed (mL)} \times \text{Dose concentration (DPM/mL)}} \times 100 \quad (9.1)$$

Figure 9.3 A representation of rat metabolic cage used for current mass balance studies for the separate collection of the urine (in bottle below) and feces (middle collection cone) for the rodents. For the metabolite profiling purpose, the samples (first 48 h) were collected over ice or frozen conditions.

Identification and quantification of metabolites of drugs in urine can be achieved using HPLC with off-line or on-line radioactivity detection and LC-MS/MS. For this purpose, urine samples can be pooled for analysis and may require to be concentrated in order to increase the detection sensitivity of the metabolites.

Feces are collected separately from urine with a modified metabolic cage for rodents, as represented in Fig. 9.3. Feces samples are subjected to homogenization, solubilization, and decolorization before radioactivity measurements. Homogenization can be done with water, buffer, bovine serum albumin solution [6], suspension agent solution, or water containing organic solvent(s). Similar to blood samples, after solubilization, decolorization is then performed with 30% hydrogen peroxide, if the solubilization method other than combusting method is used. As was the case for blood samples, EDTA (50 μ L of 100 mM) can be added as an antifoaming agent to the solubilized sample before addition of hydrogen peroxide. Finally, scintillation fluid is added to each vial. Overnight storage in a dark place is recommended before quantification of radioactivity with liquid scintillation counting to reduce chemiluminescence. The

percentage of the radioactive recovery from the feces is calculated from the weight of feces recovered, and the homogenization factor is given by expression given in Equation 9.2:

% Recovery in feces

$$= \frac{\text{Weight recovered (g)} \times \text{dilution factor (g/g)} \times \text{homogenate concentration (DPM/g)}}{\text{volume dosed (mL)} \times \text{dose concentration (DPM/mL)}} \times 100 \quad (9.2)$$

To determine the concentration of unchanged drug and/or metabolites in feces, the homogenates are processed and cleaned up using an appropriate method (such as solid-phase extraction or liquid–liquid extraction) and then analyzed by LC-MS/MS. After the final sample collection is completed, each cage is rinsed with water and 50% ethanol (or another appropriate solvent), and the resulting cage wash is quantitatively analyzed using LSC. The percentage of radioactivity recovery from the cage wash can be calculated from the ratio of volume recovered after cage wash and the concentration to the volume dosed and the concentrations recovered in cage wash, using Equation 9.3:

% Recovery from cage wash

$$= \frac{\text{Volume recovered in cage wash (mL)} \times \text{sample concentration (DPM/mL)}}{\text{Volume dosed (mL)} \times \text{dose concentration (DPM/mL)}} \times 100 \quad (9.3)$$

The detailed design of collection of samples in different matrices at different time intervals with applicable methods for the measurement of total radioactive drug, parent drug, and metabolites, with rationale and recommendations have been listed in Table 9.2.

If tritium-labeled compound is used, then tritiated water formation can be estimated to assess the metabolic stability of the radiolabel using the following equations [2]:

$$C_0 = C_{\text{mid}} \times \frac{0.693}{t_{1/2}} t$$

$$f = \frac{C_0 \times V_{\text{bw}}}{\text{dose}}$$

where C_0 is the concentration of tritiated water at time 0; C_{mid} is the concentration of tritiated water in urine at the midpoint of the collection interval; $t_{1/2}$ is the average tritiated water half-life in the rat, 85 h; t is the midpoint of the collection interval; f is the fraction of dose converted to tritiated water; and V_{bw} is the exchangeable body water volume in the relevant species.

9.4.3.3 Tissues and Organs. As part of preclinical mass balance studies employing a radiolabeled drug, tissue distribution studies are usually conducted when the disposition kinetics, distribution, and potential for accumulation of the drug and/or its metabolites in various parts of the animal body needs to be assessed [6,18]. The concepts of tissue/organ distribution studies, following administration of radiolabeled drugs in rodent, are briefly discussed in this section. The main objectives of these studies are as follows [19,20]:

1. To determine the distribution of drug-related material in various tissues/organs in the body.
2. To predict the exposure of drug-related materials at the target site of pharmacological response.
3. To investigate the potential sites involved in the metabolism.
4. To investigate the quantitative transfer across the blood–brain barrier, reproductive system, and placenta barriers.

These studies can aid in identifications of reasons for incomplete recovery of radioactivity, which may be due to reversible or irreversible tissue binding or incorporation into different organs/tissues. The use of radiolabeled compounds is extensive and very valuable in tissue distribution studies, and it is the basic requirement from regulatory agencies that preclinical animal tissue distribution data are submitted as a prerequisite for estimating the potential radioactivity exposure in clinical studies unless a trace radioactive dose with accelerator mass spectrometry (AMS) is used. Tissue distribution studies are performed to quantify the distribution of drug-related radioactivity (unchanged drugs or metabolites) in the target tissues of animal species. Typically, these studies are limited to single doses by the intended route of administration. After the administration of radiolabeled drugs, designated tissues and organs are promptly dissected after animals were sacrificed at various sampling time intervals [10], and the radioactivity was quantified using LSC. This quantification of the radioactivity by LSC in various tissues/organs can be achieved either by analyzing the homogenized tissue/organ or through combustion of tissue/organ to $[\text{CO}_2]$ that is further trapped in alkaline solution and quantified for ^{14}C radioactivity (for ^3H -labeled compound, $^3\text{H}_2\text{O}$ is trapped). The concentration of drug-related material (total radioactivity) in major tissues and organs reveals the degree of transient exposure of specific organs to the drug [20,21].

Another method to quantify tissue distribution of radioactivity into various organs/tissues is the QWBA technique [22]. QWBA is used to quantify the distribution of radioactivity in a larger extent to all body compartments, which helps target specific organs for further recovery of radioactivity as described before [3] or drug-related components, if needed. In QWBA studies, at least one animal per time interval is sacrificed at various intervals after dosing and then frozen in a “microtomb” at -20°C . Before whole-body section collection, standards fortified with ^{14}C radioactivity (as quality control) are placed into the frozen block for monitoring the uniformity of the section thickness. Then thin slides of the whole animal with a thickness of $\sim 40\ \mu\text{m}$, including representative of all major tissues, organs, and biological fluids, are prepared on adhesive tape. A section set from each animal is prepared by mounting a representative section from each level of interest. These mounted sections are exposed on phosphorimaging screens along with plastic embedded for subsequent calibration of the image analysis software. These screens are exposed for almost three days (or seven days for tritium) and then scanned using a phosphor imager to measure the radioactivity. On the basis of the body surface area and body weight, the exposure of radioactivity to each tissue and organ in rats can be scaled to human tissues for the calculation of human whole body exposure [2] and effective dose for human administration [23] (interested readers are advised to refer to Chapter 26, Volume V, for detailed explanation on quantitative whole-body

TABLE 9.3 Tissue Distribution Study Design: Quantitative Whole-Body Autoradiography with Various Rationale and Comments

Distribution (QWBA) ^a	Design	Rationale and Comments
Dose	Same as the mass balance study	Support toxicity studies Support human ADME study (dosimetry)
Time points	For example, 0.5, 1, 2, 4, 8, 24, 48, 72, and 168 h (or other time points according to pre-existing information)	Tissue distribution estimation in organs/tissues and spatial resolution
Number of animals (<i>N</i>)	<i>N</i> = 1 for each time point	Fewer animals necessary Pigmented rats with one albino at 168 h or v.v. (to investigate melanin binding in eyes or skin)

Abbreviation: v.v., vice versa.

^aUsually small animals are preferred, that is, rat and mouse, unless larger species are required. Selected organs of interest can also be collected for further analyses for the parent and/or metabolite(s).

autoradiography). The numbers of animal per study group, doses, and time intervals for both dissection and QWBA with rationale and comments have been compiled in Table 9.3.

9.4.3.4 Bile. Biliary excretion is an important elimination route and many compounds that are excreted in bile can be reabsorbed in the intestine, to complete an enterohepatic circulation cycle. The cycle can influence the absorption and elimination rate constants and alter the plasma concentration–time profile [24,25]. Bile-duct cannulation provides a way to examine the biliary excretion and potential enterohepatic circulation [26,27] and thus contributes useful information on the rate and extent of excretion of drug and/or metabolites via biliary pathways. Biliary excretion studies can be conducted by surgically ligating the common bile duct and inserting a cannula for bile collection [28] (see also Fig. 9.2). A recovery period of at least 24 h should be allowed before administering the test drug in order to avoid possible delays in gastrointestinal transit associated with postoperative adynamic ileus [29]. Tse and Ballard [26] developed a method using a pair of bile duct–duodenum cannula-linked rats, which permits a realistic approximation of biliary excretion and reabsorption in intact animals. After the acclimation period of the surgery, animals are lightly anesthetized and the continuous loop is then cut into two sections, for the bile collection and synthetic bile replacement to maintain the bile flow. A 50-cm extension tube is then attached to both sections of the continuous loop in order to pass through protective tether and spring. The animal is then placed back to metabolic cage and externalized tubing is attached to a dual channel swivel. The bile flow needs to be closely monitored for 1–2 h before the studies [30], and if possible, liver function tests can be performed by monitoring the level of alanine aminotransferase (ALT), aspartate aminotransferase (AST), and bilirubin [31]. Control bile is collected from the bile-duct cannula up to 0.5 h pre dose. After the administration of dose, synthetic bile is infused (via duodenal cannula in rodents) at a continuous rate of 1 mL/h for the duration of the study. Bile samples are collected at predefined time intervals (e.g., pre dose, 0–2, 2–4, 4–8, 8–12,

TABLE 9.4 List of Various Parameters Needed to be Considered in Designing and Handling of Bile-Duct Cannulated Animals with the Rationale and Comments

Bile-Duct Cannulation	Design	Rationale and Comments
Criteria	If >65% of radioactive dose is recovered in feces after intravenous dosing	If <65% of dose is recovered, study is conducted if there is strong interest in specific metabolites
Doses	Low for oral route (standard); <i>For intravenous route</i> : same as used in intact animals	Extent of biliary excretion/absorption/recycling
Bile substitution	Yes, method to be chosen	To avoid bile depletion
Time intervals	Bile in daily fractions up to 72 h (e.g., 0–2, 2–4, 4–8, 8–12, 12–24, 24–48, 48–72)	Maximum collection time feasible
Number of animals (<i>N</i>)	<i>N</i> = 3 for oral dosing; <i>N</i> = 2 for intravenous dosing	Means values are calculated
Volume of samples	Same as excretion studies	—
Number of measurements	Same as excretion studies	—

12–24, 24–48, and 48–72 h post dose). In addition, urine and feces are also collected in 24-h intervals for the duration of study. All excreta (urine, bile, and feces) are stored at approximately -20°C or lower until the time of analysis. After 72 h, the animals are sacrificed and the animal carcasses are retained at -20°C for further analysis as needed. To evaluate the enterohepatic circulation, the blood samples can be collected from BDC rats. The enterohepatic circulation can be estimated based on the blood or plasma exposures between BDC rats and intact rats. The enterohepatic circulation can also be accessed by introducing bile from the animal (donor) dosed with the drug to the intestine of another animal (receiver) without drug dosed. The design and handling of BDC animals are summarized in Table 9.4. The percentage of radioactivity recovered in bile is calculated from the ratio of the amount of radioactivity recovered in bile to the amount of radioactivity administered using Equation 9.4:

% Recovery from bile

$$= \frac{\text{Volume recovered in bile (mL)} \times \text{bile concentration (DPM/mL)}}{\text{Volume dosed (mL)} \times \text{dose concentration (DPM/mL)}} \times 100 \quad (9.4)$$

9.4.3.5 Carcass and CO_2 Exhalation. In some cases, the mass balance recovery is not complete, as determined from the total recovery in excreta, when compared with the administered dose. The most common reason is that the drug and/or its metabolites have a long half-life or are retained in certain tissue/organs, via, for example, irreversible binding to tissue/organ components or the incorporation of the radioisotope into endogenous components [6]. In such cases, as briefly discussed, the QWBA data may provide useful information. The radioactivity retained in the organs or carcass also can be analyzed to identify reasons for low recovery. In this method, animals are

sacrificed at the last time point, for example, 168 h, with an overdose of appropriate anesthesia and are stored at approximately -20°C pending potential analysis. Most organs can be easily homogenized and/or digested with a solubilizer. The carcass is often digested in organic alkaline solution followed by homogenization. For instance, the carcass may be digested in 30% methanolic potassium hydroxide solution (1-g sample weight per 1 mL) for approximately two days. Ethanol (two volumes of the sample weight) can be added to the solubilized sample and the net sample weight is measured for later calculation. The sample is further homogenized by a Polytron[®]. Owing to the high collagen content, a higher solvent volume to carcass weight ratio is generally required for homogenization on the large animal species, especially nonrodents, to prevent coalescing of the homogenate. An aliquot of homogenate (~ 200 mg) is taken in three to four replicates for the radioactivity determination using liquid scintillation counting to calculate the total remaining radioactivity. The percentage recovery in a carcass is calculated using Equation 9.5:

$$\begin{aligned} & \% \text{ of recovery in carcass} \\ &= \frac{\text{Total weight of solubilized material (g)} \times \text{sample concentration (DPM/g aliquot)}}{\text{Volume dosed (mL)} \times \text{dose concentration (DPM/mL)}} \\ & \quad \times 100 \end{aligned} \quad (9.5)$$

TABLE 9.5 List of Various Factors to be Considered, While Addressing Radioactivity Recovery Issues, Including Recovery From Carcass and CO₂ Exhalation with Rationale and Comments

	Design	Rationale and Comments
<i>Carcass</i>		
Criteria	If mass balance in excreta <90% (consider residual radioactivity in tissues)	Only in intact animals; Small animals preferred but mainly depend on drug under study
Method of analysis	Solubilization or homogenization and analysis using liquid scintillation counting or HPLC with radiochromagraphy detector	
Number of animals	Animals with recovery <90%	To add information about incomplete recovery
Time intervals	At the end of the study, for example, 168 h	—
<i>Expired CO₂</i>		
Criteria	If mean mass balance inclusive carcass <90%	To add information about incomplete recovery
Number of animals	$N = 2$ (only select one representative route)	—
Collection	0–12, 12–24 h <i>Optional:</i> 24–168 h in intervals metabolic cage	To avoid saturation of absorber To get mass balance recovery

Also see Fig. 9.6 for the basic considerations of troubleshooting.

If the mean mass balance including excreta and carcass is <90% for all routes and dosages and carbon dioxide is expelled as a metabolic product of the compound, one can monitor the radioactivity in the expired [^{14}C] CO_2 for more complete radioactivity recovery [32]. In a number of position of radioactive [^{14}C]-labeled compounds, the radioactivity of expired [^{14}C] CO_2 was successfully measured for the calculation of mass balance in the expired air [33]. Expired air can be collected by keeping the animals (rodents or nonrodents) in special metabolic cages in which air is drawn by vacuum pump with continuous air replacement. Exhaled air exiting the metabolic cage is passed through an appropriate trapping solution (usually alkaline solution), such as 2-methoxy-ethanol and 2-amino-ethanol (2:1) [34], and converted to nonvolatile carbonates. The trapping solution is replaced and assayed at designated times post dose so that the total radioactivity expired as labeled carbon dioxide can be determined [17,21,33]. The percentage recovery of expired radioactivity through exhalation is calculated from the concentration of radioactivity collected as carbonate using Equation 9.6:

$$\begin{aligned} & \% \text{ Recovery from } \text{CO}_2 \\ &= \frac{\text{Volume of trapping solution (mL)} \times \text{concentration (DPM/mL)}}{\text{Volume dosed (mL)} \times \text{dose concentration (DPM/mL)}} \times 100 \quad (9.6) \end{aligned}$$

Various parameters of designing and handling of radioactivity recovery in carcass and CO_2 are listed in Table 9.5.

9.5 USE, SELECTION CRITERIA, AND LIMITATIONS OF RADIOLABEL COMPOUNDS

Radiolabeled drugs have been widely used in mass balance studies since the radioactivity can be easily detected and quantified using scintillation techniques, and the disposition fate of drugs can be simultaneously characterized. The radioisotope needs to be carefully selected or designed for a successful mass balance study, along with the position of radiolabel in the compound, radiochemical purity, and the specific activity, for they can have a significant impact on the formation of metabolites and detection and thus affect the recovery of total radioactivity. For example, radiolabel isotope should be at metabolically stable position of the parent molecule such that it can stay associated with the metabolites for identification and quantification. Failure to do so not only affects the mass balance results but can also cause difficulties in differentiating endogenous compounds from the true metabolites [21]. Various radioisotopes can be used in mass balance studies, including tritium- ^3H , carbon- ^{14}C , phosphorus- ^{32}P , sulfur- ^{35}S , and iodine- ^{131}I [8,35–38]. The selected radiolabeled compound must have identical PK properties and metabolic fate as the unlabeled compound [39]. Prior knowledge of the metabolism of a compound (or known analogues) obtained from *in vitro* metabolism studies and/or *in silico* predictions can assist in determining the optimum radiolabeled positions and isotopes. Ideally, the same radiolabeled compound is used in both the preclinical and clinical mass balance studies, making human mass balance data more comparable to preclinical studies. ^3H and ^{14}C are the most commonly used isotopes in most of the mass balance studies. If heavier radioisotope are selected rather than ^{14}C and ^3H , the corresponding kinetic isotope effect needs to be considered because metabolic conversion can be affected by change in reaction

kinetics, as a result of the formation of strong chemical bonds by heavier isotopes [40]. ^{14}C is a preferred isotope due to its physiochemical stability, longer decay half-life, and higher radiation energy for better analytical sensitivity. Carbon ^{14}C has eightfold more energetic β -radiations (electrons) than that of tritium ^3H (0.156 vs 0.019 MeV), and thereby the detection sensitivity of ^{14}C is higher than ^3H . On the other hand, tritium-labeled isotope allows for a less expensive and more rapid chemical synthesis in most cases and a higher specific activity can be achieved (29.1 Ci/milliatom) than with ^{14}C (62.4 mCi/milliatom) [7,40]. These advantages may be useful for the early development stage and studies with a need of very small amounts of a compound. However, the major disadvantage of ^3H is its tendency to be exchanged with hydrogen in aqueous matrices, resulting in unlabeled compounds, especially when ^3H is bonded to a heteroatom or α -positioned to a double-bonded heteroatom [40,41]. If the drug compound has a large molecular weight (>700 g/mol), it is likely the molecule will divide into two metabolic moieties. The molecule can be dually labeled with ^3H and ^{14}C atoms to the designated moiety, respectively, and, thereby each moiety can be traced independently [21]. For either ^3H - or ^{14}C -labeled drug at the metabolically stable position, radiochemical purity is preferred $>98\%$ and should not be $<95\%$. The purity of the radiolabeled drug should be validated before the dose preparation, and stability of the radiolabeled drug under conditions of administered should be checked at predose and postdose time points [2].

9.6 DETERMINATION AND ANALYSIS OF MASS BALANCE AND PHARMACOKINETIC PARAMETERS

The main purpose for conducting the mass balance studies is to determine the mass recovery of administered radioactive dose, identify major metabolites and excretory pathways, and characterize the PK profile of the drug compound by means of measuring the concentration of parent drug/metabolites or total radioactivity in blood, plasma, urine, bile, and feces. In order to confirm the validity of mass balance results, these PK parameters obtained from the mass balance study can be compared with those from preclinical toxicity studies. All PK parameters for total radioactivity and parent drugs can be calculated with the software programs (e.g., WinNonlin), using non-compartmental or compartmental analysis method. For the p.o. dose, highest average plasma concentration ($C_{\max}$) and times to achieve this peak concentration ($T_{\max}$) are recorded directly from experimental observations for the drug and its metabolites. The radioactivity in blood and plasma is measured separately using LSC. These measured radioactivity parameters are also called *pseudo-pharmacokinetic parameters* and are calculated in the same manner as those of parent drug. The ratio of AUC of unchanged, intact parent drug versus the AUC of total radioactivity gives a measure of metabolites formation and their importance in drug disposition. The $\text{AUC}_{(0-\text{last})}$ is calculated using the linear trapezoidal rule, whereas $\text{AUC}_{(0-\infty)}$ is calculated using the Equation 9.7 as

$$\text{AUC}_{(0-\infty)} = \text{AUC}_{(0-\text{last})} + \frac{C_{(\text{last})}}{\lambda_z} \quad (9.7)$$

Here, the slope (λ_z) is derived from the slope of the log-linear line from at least the last three data points. This is used to calculate the half-life ($t_{1/2}$). Distribution half-life and elimination half-life are calculated to predict the accumulation in different

compartments and elimination time of the drug. The elimination half-life ($t_{1/2}$) of radioactivity in the plasma is important in selecting the time interval and further aid in determining the study end point, maximize the radioactive recovery in mass balance studies, and also assess the risk of accumulation of metabolites after multiple dosing [4]. Comparing the half-life of parent drug with that of total radioactivity gives a better understanding of the accumulation of the metabolites (*note*: detection sensitivity also needs to be taken into consideration). For the i.v. dose, the concentration of parent compound at time zero $C_{(0)}$, is back-extrapolated, based on a log-linear regression. The apparent volume of distribution at steady state (V_{ss}) is calculated from the i.v. data using expression given by Equation 9.8:

$$V_{ss} = \frac{\text{dose}_{(i.v.)} \times \text{AUMC}_{(0-\infty)}}{[\text{AUC}_{(0-\infty)}]^2} \quad (9.8)$$

where $\text{AUC}_{(0-\infty)}$ and $\text{AUMC}_{(0-\infty)}$ are the area under the concentration–time curve and area under the first moment concentration–time curve from time zero to infinity, respectively.

The total body clearance (CL_t), renal clearance (CL_r), biliary clearance (CL_b), and hepatic clearance (CL_h) can be calculated using following expressions.

The total systemic clearance (CL_t) is estimated from the ratio of dose divided by $\text{AUC}_{(0-\infty),(i.v.)}$ from the parent dose after i.v. dose and is given by Equation 9.9 [42]:

$$\text{CL}_t = \frac{\text{dose}_{(i.v.)}}{\text{AUC}_{(0-\infty),(i.v.)}} \quad (9.9)$$

In most cases, drug concentrations are measured in plasma rather than in blood, because sample preparation and drug analysis in plasma are simpler than in blood and this total systemic clearance is defined as equal to the total systemic plasma clearance, unless otherwise indicated in the text.

Renal clearance (CL_r) can be estimated from amount of unchanged parent dose excreted in urine over an extended period of time dividing by $\text{AUC}_{(0-t)}$ of parent drug after i.v. dose and is given by Equation 9.10 [42]:

$$\text{CL}_r = \frac{\text{Amount of parent drug excreted in urine up to time } t}{\text{AUC}_{(0-t),(i.v.)}} \quad (9.10)$$

The urine collection time should be long enough to account for almost the entire parent drug excreted in urine in order to get a reliable estimate of the CL_r . Additionally, it is desirable that $\text{AUC}_{(0-t)}$ is greater than 90% of $\text{AUC}_{(0-\infty)}$.

Biliary clearance (CL_b) of a drug is experimentally determined from the ratio of the amount of parent drug excreted in the bile versus the $\text{AUC}_{(0-t),(i.v.)}$ of parent drug after i.v. dose and is given by Equation 9.11 [42]:

$$\text{CL}_b = \frac{\text{Amount of parent drug excreted in bile from time 0 to } t}{\text{AUC}_{(0-t),(i.v.)}} \quad (9.11)$$

where $\text{AUC}_{(0-t),(i.v.)}$ is the AUC in plasma from the time 0 (zero) to t hours, and t is usually more than 24 h for sufficient bile collection after i.v. administration of a drug.

Clearance from different routes are additive and systemic or total clearance is given by the sum of individual organ clearances [43]. Assuming that the respiratory and extracorporeal clearances are negligible, hepatic clearance (CL_h) can be estimated by subtracting the sum of the renal and bile clearance ($CL_r + CL_b$) from the total clearance (CL_t) as expressed by Equation 9.12:

$$CL_h = CL_t - (CL_r + CL_b) \quad (9.12)$$

Equation 9.13 assumes that nonrenal and nonbiliary clearances may be due to liver metabolism. The cumulative percentage of collected radioactivity recovery from different matrixes (urine, feces, bile, cage wash, carcass, and expired air) gives the estimate of total mass balance recovery for any compound when compared with the dose administered, that is:

Total % radioactivity recovered = % of radioactivity recovered in urine (Eq. 9.1) + % of radioactivity recovered in feces (Eq. 9.2) + % of radioactivity recovered from cage wash (Eq. 9.3) + % of radioactivity recovered from bile (Eq. 9.4 is only applicable for BDC rats) + % of radioactivity recovered from carcass (Eq. 9.5) + % of radioactivity recovered from expired air (Eq. 9.6).

Table 9.6 summarizes the different methods for the calculation of various parameters from the mass balance study design with rationale and comments.

In addition, the mass balance studies can also determine the following other parameters from intact and BDC animals:

1. percent of radioactivity retention in different organs at any time during the study or at the end of the study,

TABLE 9.6 List of Factors to be Considered for Pharmacokinetic Parameters Analysis in Mass Balance and ADME Studies

Design	Calculations	Rationale and Comments
Pharmacokinetics of radiolabeled in blood and plasma	C_0 , $C_{\max}$, $T_{\max}$ observed; $AUC_{(0-168h)}$ and $AUC_{(0-\infty)}$; $t_{1/2}$ terminal half-life %; absorption (fraction absorbed, F_{abs})	With i.v. dosing determine C_0 ; With oral dosing determine $C_{\max}$, $T_{\max}$; Estimation of exposure; Prediction of accumulation of the drug-related radioactivity; Estimation of fraction absorbed; Comparison to toxicity studies; Comparison to other species
PK of unchanged drug in blood or plasma	C_0 , $C_{\max}$, $T_{\max}$ observed; $AUC_{(0-168h)}$ and $AUC_{(0-\infty)}$; Distribution and/or elimination half-life; CL , V_{ss} , MRT	Prediction of drug behavior Oral bioavailability First-pass estimate
Radioactivity in urine, bile, feces, cage wash, and carcass in rodents, if recovery in excreta is low	Cumulative % of dose % mass balance recovery % absorption (fraction absorbed, F_{abs})	Contribution of excretion route; Estimation of fraction absorbed for permeability classification needed for potential FDA biowaivers

Abbreviation: MRT, mean residence time.

2. level of parent drug and its metabolites in the target organs,
3. ratio of radioactivity exposure in organs (AUC_{organ}) and in plasma (AUC_{plasma}), and
4. fraction absorbed (F_{abs}) across the gastrointestinal barrier.

Oral bioavailability ($F\%$) gives an estimate for the extent of absorption and first-pass metabolism and it can be calculated from the ratio of exposure of parent drug after an p.o. dose to the parent drug exposure after an i.v. dose. Some reports have stated that the area under the curve (AUC) obtained from plasma radioactivity [21] can be used to calculate bioavailability, but it is not valid for the compounds with high first-pass metabolism. Tse and Laplanche [44] had already demonstrated the differences in the amount of drug-related material absorbed and the systemic bioavailability of the parent drug using the radioactivity.

The bioavailability ($F\%$) is estimated from the calculated AUC after the p.o. and i.v. administrations of parent drug using the Equation 9.13:

$$F\% = \frac{AUC_{(0-\infty), (p.o.)} \times \text{dose}_{(i.v.)}}{AUC_{(0-\infty), (i.v.)} \times \text{dose}_{(p.o.)}} \times 100 \quad (9.13)$$

The fraction absorbed or absorption (F_{abs}) can be calculated from the ratio of $AUC_{(0-\infty)}$ after the p.o. and i.v. administrations of total blood/plasma radioactivity using the same equation as for $F\%$.

This maximum fraction absorbed can be used to distinguish the drug on basis of permeability classification, which can be served as an important tool for potential FDA biowaivers. In some cases, the radioactivity excreted in urine can be used to calculate F_{abs} . Various other methods that can be used for the calculations of fraction absorbed are listed in Table 9.7 along with the limitations and recommendation.

TABLE 9.7 Different Methods for Estimation of Absorption and Bioavailability from Calculated Parameters of the Intact Parent Drug or Radiolabeled Drug, Total Radioactivity

Estimation of Percent Absorption or Fraction Absorbed (F_{abs})	Equation	Comments and Limitations
F_{abs} calculated from total blood/plasma radioactivity amount	$F_{\text{abs}} = \frac{AUC_{(0-\infty), (p.o.)} \times \text{dose}_{(i.v.)}}{AUC_{(0-\infty), (i.v.)} \times \text{dose}_{(p.o.)}}$	Not valid for a compound with high first-pass metabolism
F_{abs} calculated from total cumulative urinary radioactivity recovery ratio (p.o. vs i.v.)	$F_{\text{abs}} = \frac{D_{(\text{urine}), (p.o.)}}{D_{(\text{urine}), (i.v.)}}$	Minimal absorption; best suited for compounds with renal excretion >10%
F_{abs} calculated from bile-duct cannulated animals	$F_{\text{abs}} = \frac{D_{(\text{urine}), (p.o.)} + D_{(\text{bile}), (p.o.)}}{D_{(\text{urine}), (i.v.)} + D_{(\text{bile}), (i.v.)}}$	Value represents minimal absorption
F , oral bioavailability from intact parent drug, ideally in a crossover design	$F = \frac{AUC_{(0-\infty), (p.o.)} \times \text{dose}_{(i.v.)}}{AUC_{(0-\infty), (i.v.)} \times \text{dose}_{(p.o.)}}$	Assumes CL is independent of dosing routes and dose amount

D , fraction of the dose recovered from urine or bile.

9.7 CASE EXAMPLE FOR MASS BALANCE STUDY IN PRECLINICAL SPECIES

9.7.1 Compound A—Experimental Design

For compound A, preclinical mass balance studies were designed based on the methodology as described in Tables 9.1–9.5. The dose used was 5 mg/kg for the i.v. dose and 50 mg/kg for the p.o. dose for both the intact rat and BDC rat studies. The radiochemical purity was >99% for all study groups.

9.7.2 Compound A—Pharmacokinetic Parameters

All PK parameters for compound A were calculated based on the designs as discussed in Table 9.6. The time versus plasma concentration profile of unchanged compound A along with compound A-related total radioactivity after i.v. dosing and p.o. dosing are presented in Figs. 9.4 and 9.5, respectively. The maximum concentration ($C_{\max}$) for parent compound A observed in plasma is 950 ng/mL, which is achieved at 2 h post p.o. dosing, indicating a moderate absorption rate. Other observed and calculated PK parameters in different matrices are summarized in Table 9.8 for both p.o. and i.v. doses. The ratio of $AUC_{(0-\infty)}$ of parent drug versus $AUC_{(0-\infty)}$ of radioactivity is ~55%, indicating that some amount of metabolite(s) were formed from compound A and present in the blood circulation.

9.7.3 Mass Balance Parameters and Interpretations

The percentage of dose recovered for unchanged compound A in different matrices is shown in Table 9.9: All mass balance parameters were calculated from the derived equations (Eqs. 9.1–9.6) and using the methodology discussed in Table 9.6. As shown, compound A is predominantly eliminated as unchanged drug (57–69% of the total dose) in urine and feces. The major portion of the drug is recovered in feces with a

Figure 9.4 Plasma drug concentration versus time profile of parent (unlabeled) drug and radioactivity (labeled) drug after the intravenous dose. Concentration of unlabeled drug is given in units of ng/mL and concentration of labeled drug is given in units of ngEq/mL, respectively.

Figure 9.5 Plasma drug concentration versus time profile of parent (unlabeled) drug and radioactivity (labeled) drug after the oral dose. Concentrations of unlabeled drug is given in units of ng/mL and concentration of labeled drug is given in units of ngEq/mL, respectively.

TABLE 9.8 Pharmacokinetics Parameters of Unchanged Parent Compound A or Compound A-Related Radioactivity After Intravenous Dosing (5 mg/kg) and Oral Dosing (50 mg/kg) in Rats

PK Parameters	$C_{\max}$ (ng/mL or ngEq/mL) ^a		$T_{\max}$ (h)	AUC _(0-∞) (ng · h/mL or ngEq · h/mL) ^a		CL (L/h/kg)	V_{ss} (L/kg)	$F\%$ or F_{abs}	$t_{1/2}$ (h)

^aConcentration units are ng/mL for parent and ngEq/mL for radioactivity. $C_{\max}$ after intravenous dosing is referred to as C_0 .

TABLE 9.9 Unchanged Parent Compound A Recovered in Different Matrices

% Dose Recovery (Unchanged Drug)	Intact Rats		Bile-Duct Cannulated Rats	
	i.v.	p.o.	i.v.	p.o.
Excretion in urine	18	3.0	19	3.1
Excretion in feces	39	66	11	53
Excretion in bile	N/A	N/A	35	8.0
Total recovery (%)	57	69	65	64
CL _r (L/h/kg)	0.60	—	0.62	—
CL _t (L/h/kg)	3.1	—	—	—

Abbreviation: N/A, not applicable.

smaller amount in the urine following both routes of administration. The portion of unchanged parent compound A excreted in urine is approximately the same in intact and BDC rats after administration of both doses (19% for i.v. and ~3% for p.o.). As expected, the recovery in feces after i.v. dosing is lower in the cannulated compared to the intact rats (11% vs 39%), indicating biliary excretion of compound A, which was 35%. The renal clearance, CL_r , is comparable (~0.6 L/h/kg) between the intact and BDC rats.

The percentage of dose recovered as total radioactivity in different matrices is shown in Table 9.10. In intact rats, the fecal excretion of the radioactivity is dominant after both dosing routes accounting for 74% of dose after i.v. administration and 93% of dose after p.o. administration. The urinary radioactivity excretion is minor, accounting for 20% of the i.v. dose and 4% of p.o. dose, and is consistent in both intact and BDC rats. On the basis of combined biliary (21%) and renal excretion (5%), the absorption after p.o. dosing is estimated to be at least 26% for compound A, which is comparable to the values estimated from total plasma or blood radioactivity data (26–29%). The mass balance of radioactive dose recovered in excreta, including the cage wash is calculated using Equations 9.1–9.6 and is completed (~100%) within 168 h post dose. From these obtained parameters of the mass balance recovery, the calculation for various other parameters such as bioavailability, fraction absorbed, total clearance, renal clearance, biliary clearance, and hepatic clearance can be calculated based on Equations 9.9–9.13 and are listed as follows:

- The estimation of p.o. bioavailability of compound A, calculated from the parent drug using Equation 9.13, is ~25%, which is low.
- The estimation of fraction absorbed, calculated from the total radioactivity using Equation 9.13, is 26% (plasma) to 29% (blood), indicating that the absorption of compound A in rats is low and incomplete.
- The estimation of total clearance from the total exposure of the parent drug with time curve and the total dose administered i.v. calculated using Equation 9.9 is 3.1 L/h/kg, which indicates a high plasma clearance for compound A.
- The renal clearance is calculated by dividing percentage of parent drug recovered in urine after i.v. administration by the area of concentration under the curve with time, using Equation 9.10, and is 0.6 L/h/kg, which is 19% of the total clearance.

TABLE 9.10 Mass Balance Parameters for Compound A, Radioactivity Recovery in Different Matrices

% Dose Recovered (Radiolabeled Drug)	Intact Rats		Bile-Duct Cannulated Rats	
	i.v.	p.o.	i.v.	p.o.
Excretion in urine	20	4.0	21	5.0
Excretion in feces	74	93	16	74
Excretion in bile	N/A	N/A	63	21
Cage wash recovery	2.0	1.0	1.0	1.0
Total recovery (%)	96	98	101	101

Abbreviation: N/A, not applicable.

- The biliary clearance can be estimated from percentage of parent drug excreted in bile after i.v. administration, divided by the area of concentration under the curve with time, from the BDC rats, using Equation 9.11, and is 1.2 L/h/kg, indicating that 39% of total clearance is through bile.
- The hepatic clearance is calculated by subtracting the cumulative renal and bile clearance from the total clearance using Equation 9.12 and is 1.3 L/h/kg, suggesting that ~42% of the total clearance is hepatic clearance, suggesting that the drug is not extensively metabolized.

9.8 COMMON ISSUES DURING CONDUCT OF PRECLINICAL MASS BALANCE STUDIES

The most common challenge in mass balance studies is a low mass recovery of radioactivity. Theoretically, complete mass balance studies would require that 100% of the radioactivity administered should be recovered from excreta and cage wash, which is rarely possible. The most common reasons are that the excreta is not completely collected during the study, contributing to the loss of radioactivity balance collection, especially if the loss occurs within a period of high excretion rate of drug-related material [14]. As a rule of thumb, excreta samples need to be collected until the recovery is <1% of administered radioactivity in urine and feces for two consecutive days [4]. In the case for compounds with a long elimination half-life, as indicated by a prolonged retention of the radioactivity in blood, the sample collection period requires to be extended. Some other issues can influence the recovery of mass balance. Position of the radionuclide within the drug molecule should be carefully considered in order to prevent a labeled fragment of the drug from entering endogenous compound

TABLE 9.11 Reasons for Low Radioactivity Recovery with Proposed Recommendations

Reason for Low Recovery	Proposed Recommendation
<i>Artificial reasons</i>	
Inaccurate dose	Careful consideration in dose preparation and administration
Incomplete collection of excreta	Use of modified cages; collection of excreta until 1% recovery for consecutively two days
Portion of dose lost in vomiting (without collection)	Careful observation is needed after the oral administration
Long half-life ($t_{1/2}$) of radioactivity, long collection period, or diluted sample with drug concentration below the LOQ	Use of sophisticated analytical tools is recommended to obtain the maximum recovery
<i>Scientific reasons</i>	
Position of radioisotope in molecule, which is lost in expired air	If the recovery is below 80%, it is recommended to measure the radioactivity in the expired air
Tissue binding and noncovalent sequestration	Must be carefully studied for the parent drug and its metabolites from the preclinical studies

Abbreviation: LOQ, limit of quantification.

metabolism and also to prevent its conversion to a volatile metabolite as $^{14}\text{CO}_2$ [14], resulting in incomplete mass balance recovery. For lipophilic drugs that have low recoveries in urine and feces, the compounds can suffer from significant nonspecific adsorption to the collection containers. Mass balance studies provide limited information regarding the covalent binding to tissue macromolecules or to the blood proteins, which may account for a low mass recovery compared to total drug administered. The potential causes for low mass balance recoveries from preclinical and human studies are summarized in Table 9.11, and the reader is referred to a review article by Roffey

Figure 9.6 Basic considerations for the troubleshooting of low recovery issues in mass balance studies, usually conducted in rodents.

et al. [14]. Basic troubleshooting steps for mass balance studies with low recovery are listed in Fig. 9.6. In some BDC rat studies, the percent of radioactivity recovered in urine may be significantly higher when compared to that in intact rats even when the bile flow is in the normal range. This might be due to the alternation in the liver physiology (such as the changes in liver function, the expression of enzymes, and transporters) after bile-duct cannulation. In such cases, the data interpretation should be carried out with care and more analysis should focus on the results from the intact rats. As discussed, plasma samples may be taken for rat liver function tests before the bile study is conducted.

9.9 HUMAN MASS BALANCE STUDIES

After obtaining information of toxicity, PK, metabolite profiling, and organ/tissue radioactive exposure from preclinical mass balance studies, human mass balance studies can be conducted. These studies are required for small molecules by regulatory agencies before new drug application (NDA) filings and the mass balance data together with metabolite information is also important for the design of the clinical trials. The estimated timeline for conducting human mass balance studies is described in Fig. 9.1, which shows that the human mass balance studies are initiated once the phase 1 trials have been conducted and should be finished before the commencement of phase 2 trials. It is important to understand the metabolite profile of drugs in human and animal species as early as possible since both the ICH M3 (R2)[45] and the FDA [5] guidances highlight the need for providing safety data on human metabolites. Some metabolites are not much of toxicological concerns (e.g., most glutathione conjugates and glucuronides, except acylglucuronides). In general, ICH M3 (R2) recommends conducting the safety evaluation studies in preclinical species for metabolites that contribute more than 10% of total drug-related exposure and at significantly greater levels in human than the maximum exposure observed in the toxicity studies. The FDA guidance recommends that metabolites with an AUC exceeding 10% of the intact parent drug AUC will require toxicological evaluation in preclinical species. Because the use of radiolabeled drug in human mass balance studies adds more complexity, these studies are performed in accordance with the following codes and guidelines: Title 21, Part 56 CFR (Institutional Review Board Approval) [46]; Title 21, part 50 CFR (Protection of Human Subjects) [47]; the principles of the Declaration of Helsinki and its amendment; and Good Clinical Practice, in addition to standard International Conference on Harmonization (ICH) guidelines. For the studies to be conducted in the European Union (EU), European guidelines [48,49] are recommended to be followed. Before conduct all studies that include the use of radioisotope must be approved by the Administration of Radioactive Substances Advisory Committee (ARSAC). While these existing regulatory guidelines primarily focus on the safe and effective dose of radioactivity, in terms of exposure of ionizing radiations to various tissues/organs, to ensure “safe and effective” use of radioactive drugs [50], they do not state any acceptable criteria for total radioactivity recovery. Acceptable values for recovery, such as 85% [51] and 90% [4,14] have been proposed, but there is no widely accepted and defined cutoff value with a compelling underlying rationale [14]. The main objective of human mass balance studies is to establish the route of elimination of radioactive compounds and to compare the metabolites pattern in excreta, blood, and plasma with those obtained

from previously conducted preclinical mass balance studies for the safety exposure assessments. The nature of these studies is not intended for statistical evaluations, and ethics issues dictate the use of limited number of subjects [2]. Typically 3–8 subjects, aged 15–65 years, participate in human mass balance studies. It should be noted that conducting mass balance studies in children and pregnant women is virtually impossible due to the ethical issues, even though the drug disposition in these two groups differs significantly from the average population [52]. For anticancer drugs (mutagenic, carcinogenic, or teratogenic), healthy subjects are usually not used—patient subjects are needed for these mass balance studies. After at least an 8-h overnight fasting, in general, each subject receives a single clinically relevant dose of [^{14}C] drug containing 50–100 μCi of radioactivity. If [^3H] drug is administered the higher dose of radioactivity (50–1000 μCi) is needed to detect the low energy β -radiation of [^3H] [4]. The human radioactive dose must be evaluated for safety radiation exposure, using tissue distribution data from preclinical mass balance studies. Extrapolation of these data to humans allows the estimation of effective organ exposure to the radioactivity that is used for regulatory evaluation [50,53]. Mass balance studies in humans with the aid of the radiolabeled drug provide the total fate of drug-related material [7]. The projected human radiation exposure to selected radioisotope is estimated by direct extrapolation from the radioactivity exposure data obtained from the preclinical tissue distribution study (QWBA) based on body weight ratio [19] or drug exposure ratio (clinical plasma data compared to rat QWBA), with the assumption that drug-associated radioactivity is distributed and eliminated from the tissues in comparable manners between animal species and humans.

AMS can deliver analytical sensitivity far in excess of most other tools and has been applied to the preclinical and clinical mass balance studies [4,54]. The radiation risk, therefore, is not a concern for the study using AMS due to its low radioactive dose (tracer) and dosimetry data are not required. The high cost and low throughput are major disadvantages. The structure of metabolites should still be characterized by other analytical techniques unless the authentic reference compounds are available for coelution.

9.10 HUMAN DOSIMETRY CALCULATIONS

The purpose of the following section is to describe the various methods for the estimation of the human radioactive dose from preclinical mass balance studies using various calculation methods, which are also required for ARSAC approval (EU) to ensure the safety and efficacy after a human radioactive dose. The use of radiolabeled compounds in humans is also required to comply with the principles of As Low As Reasonably Acceptable (ALARA). International Commission on Radiological Protection (ICRP) [55] have modified the World Health Organization (WHO) exposure categories and made required the calculation of effective dose (E) [56]. This extrapolation of parameters obtained from preclinical mass balance studies to human organs is further based on the following factors:

1. the known human plasma level of the intact parent compound,
2. the observed ratio of radioactive compound relative to the parent compound in animals, and

3. the ratio of radioactivity in individual organs relative to the radioactivity in plasma for preclinical species.

The revised recommendations for radiological protection in ICRP publication-103 formally replace the previous ICRP publication-60 recommendations, and the reader is advised to follow the new guidelines to control the exposure from the radiation sources. The guidelines, provided by the U.S. Nuclear Regulatory Commission (USNRC), Part-20 of Standards for Protection against Radiation [56,57], which specify the list of different tissues/organs that are more susceptible to radiation damage and are required to be considered. Because of their susceptibility to damage, each organ is given a different weighing factor (W_T), by which the equivalent dose in various tissues/organs (T) is calculated. W_T represents the relative contribution of radioactivity in each defined tissue/organ and considers this information when calculating the total body radioactivity exposure, probability of fatal and nonfatal cancer, severe hereditary effects, and relative length of life lost. The ICRP publication-103 [58] and the U.S. Nuclear Regulatory Commission (USNRC), Part-20 of Standards for Protection against Radiation [56,57] have updated the radiation and tissue weighing factors based on the latest scientific information available and it is advised to follow these recommendations in both academia and industry. The list of specified tissues and their recommended weighing factor from ICRP-60, ICRP-103, and USNRC, Part-20 are listed in Table 9.12. For tissues/organs containing radioactivity, the exposure is calculated as the area under the radioactivity time curve (AUC) of the radiolabeled compound in the tissues/organs. Exposure in excretory organs, for example, gastrointestinal tract and bladder, is determined by the total radiation amounts in excreta (urine, bile, and intestinal contents) and the mean organ residence time in humans [20].

9.10.1 Dosimetry Calculations

The calculations for the human radiolabeled dose of [^{14}C] drug are carried out using the equations given below. The equations are derived based on the recommendations of the ICRP (Limits for intakes of Radionuclide by Workers, Radiation Dose to patients from Radiopharmaceuticals) [56,60,61]. The units of curies (Ci), as opposed to the International System of Units, Becquerel (Bq), usually express the radioactive dose. The conversion of these units is $1 \text{ mCi} = 37 \text{ MBq}$ and $1 \text{ Bq} = 60 \text{ DPM}$, where DPM means disintegrations per minutes. The fundamental equations derived for the calculation of the equivalent dose [59,62], which can be taken up in a given organ or tissue for [^{14}C] drug, are given as follows:

$$H_t = E \times f \times \text{AUC}$$

where

H_t = equivalent dose (mSv)

E = mean particle energy (MeV), and calculated for [^{14}C], $\text{MeV} = 0.050$

f = conversion factor = $\frac{\text{mSv} \times \text{g}}{\mu\text{Ci} \times \text{d} \times \text{MeV}}$ and calculated for [^{14}C], $f = 512$

AUC = time (d = day) integral of [^{14}C] drug concentration in target organ ($\mu\text{Ci d/g}$).

TABLE 9.12 List of Specified Tissues and Their Weighting Factors by ICRP Publication 60, ICRP Publication 103, and the US Nuclear Regulatory Commission Part-20^a

Name of the Tissue	Weighting Factor (W_T)		
	ICRP-60, Tables 2 and S-2	ICRP-103, Tables B.2 and B.3.5	USNRC Part-20, Sec. 20.1003
Gonads	0.20	0.08	0.25
Lower large intestine (colon)	0.12	0.12	NA
Lung	0.12	0.12	0.12
Red bone marrow	0.12	0.12	0.12
Stomach	0.12	0.12	NA
Bladder	0.05	0.04	NA
Breast	0.05	0.12	0.15
Liver	0.05	0.04	NA
Esophagus	0.05	0.04	NA
Thyroid	0.05	0.04	0.03
Bone surface	0.01	0.01	0.03
Skin	0.01	0.01	NA
Brain	NA	0.01	NA
Salivary glands	NA	0.01	NA
Kidney	NA	NA	NA
Remainder	0.05 ^b	0.12 ^c	0.30 ^d

Abbreviation: NA, not applicable.

The weighting factors are expressed as a fraction. The sum of the weighting factors is equal to 1.

^aRef. 57–59.

^bThe remainder is composed of the following additional tissues and organs: adrenals, brain, upper large intestine, small intestine, kidney, muscle, pancreas, spleen, thymus, and uterus.

^cThe remainder is composed of the following additional tissues and organs: adipose tissue, adrenals, connective tissues, extrathoracic airways, gallbladder, heart wall, kidney, lymphatic nodes, muscle, pancreas, prostate, small intestine wall, spleen, thymus, and uterus.

^dThe remainder 0.30 results from 0.06 for each of the five remainder organs that receive the highest dose (excluding the skin and lens of the eye).

After inclusion of the radiation energy, for practical use, the formula for the equivalent dose H_t for any organ or tissue is

$$H_t = k \times \text{AUC}_{(0-\infty)}$$

where k is the dose constant, and calculated for [¹⁴C], $k = \frac{\text{mSv} \times \text{g}}{\mu\text{Ci} \times \text{d}} = 25.6$.

The integration of the [¹⁴C] drug concentration–time function for the period zero to infinity is equal to the area under the [¹⁴C] drug concentration equivalent–time curve, $\text{AUC}_{(0-\infty)}$ ($\mu\text{gEq d/g}$), in the organ multiplied by the specific radioactivity (s):

$$\text{AUC}_{(0-\infty)} = s \times \text{AUC}_{(0-\infty)(\text{organ})}$$

where s is the specific activity of radioactivity ($\mu\text{Ci}/\mu\text{g}$).

Thus, the equivalent dose in any human organ or tissue (H_t) is calculated from the product of dose constant, specific radioactivity, and $\text{AUC}_{(0-\infty)(\text{organ})}$ as expressed in Equation 9.14:

$$H_t = k \times s \times \text{AUC}_{(0-\infty)(\text{organ})} \quad (9.14)$$

9.10.2 Dose Calculation for the Gastrointestinal Tract

The organs/tissues of the gastrointestinal tract are mostly exposed to the radioactivity present in the luminal contents of the organs and irradiating the organ wall. With the geometry factor of 0.5 and a defined organ residence time (τ) in the gastrointestinal tract segments, the organ equivalent dose, H_t (wall dose) is calculated by a modified formula from ICRP publication 53 [61] and expressed as Equation 9.15:

$$H_t = A \times F \times \frac{kt}{2m} \quad (9.15)$$

where

A = administering radioactivity dose (μCi)

F = fraction of the administered dose passing through the considered segment of the gastrointestinal tract

k = dose constant, and calculated for [^{14}C], $k = \frac{\text{mSv} \times \text{g}}{\mu\text{Ci} \times \text{d}} = 25.6$

τ = residence time given in days (d)

m = organ content weight given in grams (g).

As recommended by ICRP guidelines [60,61], the organ content weights and organ residence times in different organs for the human are summarized in Table 9.13. In the small intestine, the radioactivity exposure decreases due to absorption, and if absorption is a mono-exponential process, the decrease in radioactivity exposure in the small intestine is described by

$$A(t) = A^* e^{-\lambda t}$$

where A = radioactivity entering the small intestine (μCi) $A(t)$ = radioactivity remaining unabsorbed after time t , and passing to large intestine (μCi) λ = rate constant.

In that case, the equivalent dose of the small intestine is proportional to the time integral of the radioactivity present in the small intestine during the residence time τ and can be expressed as

$$H_t = A \times F \times \frac{k}{2m} \times \int_0^{\tau} e^{-\lambda t} dt$$

TABLE 9.13 List of Organ Content Weight and Organ Residence Time in Human

Organ	Organ Content Weight (g)	Organ Residence Time (h)	(d)	$k \cdot \tau / 2m^a$ (mSv/ μCi)
Stomach	250	1	0.0417	0.00213
Small intestine	1040	4	0.167	0.00205
Upper large intestine	220	13	0.542	0.03152
Lower large intestine	135	24	1.0	0.09481
Renal tract	1400	24	1.0	0.00914

^a m is organ content weight given in grams (g), τ is in units of days (d), k is 25.6 for ^{14}C .

From the limit 0 to τ after integration, this can be expressed as

$$H_t = A \times F \times \frac{k}{2m} \times \frac{1 - e^{-\lambda t}}{\lambda}$$

The rate constant, λ , is calculated by the following expression:

$$\lambda = \frac{\ln(A) - \ln(A\tau)}{\lambda}$$

9.10.3 Dose Calculation for Other Organs and Tissues

The equivalent dose (H_t) for any organ or tissue is calculated according to the general Equation 9.14. For the reference plasma, the equivalent dose H_{plasma} is

$$H_{\text{plasma}} = k^* s^* \text{AUC}_{(0-\infty)(\text{plasma})}$$

For individual organs and tissues in humans, the equivalent doses H_t are calculated based on the equivalent dose in plasma multiplied with the organ factor R_t , which is the ratio of $\text{AUC}_{\text{tissue}}$ to $\text{AUC}_{\text{plasma}}$ of radiolabeled drug from animal data. The factor R_t can be determined from the animal organ/tissue distribution data. For a detailed explanation, the R_t values from a rat tissue distribution study are summarized in Table 9.14, which are used to estimate tissue exposure in human, assuming comparable organ distribution patterns in rat and human. Thus, equivalent dose for human can be calculated from the modified Equation 9.16 and expressed as

$$H_{t(\text{human})} = H_{\text{plasma}(\text{human})} \times R_t \quad (9.16)$$

9.10.4 Effective Dose

According to the ICRP publication-60 and ICRP publication-103 [Recommendations of the ICRP, Annals of the ICRP (1991 and 2007)] [23,56,58], the whole-body effective dose (E , in units of mSv) is the sum of the weighted equivalent doses of individual tissue/organs. The effective dose is determined from the individual organs and tissues equivalent doses, H_t , using Equation 9.17. It is recommended to be <1 mSv to fall in the minor to intermediate exposure effect category set by WHO. The comparisons of weighing factors for different tissues/organs recommended by ICRP publication-60 and revised ICRP publication-103 and USNRC Part-20 is listed in Table 9.12. The ICRP publication-60 specifies 12 tissues/organs (Table 9.12) that must be taken into consideration because of their susceptibilities to radiation damage and the remainder is composed of adrenals, brain, upper large intestine, small intestine, kidney, muscle, pancreas, spleen, thymus, and uterus. In a more recent ICRP publication-103, brain and salivary glands were added to the mandatory organs (Table 9.12), thus making them a total of 14 and the remainder is composed of adipose tissue, adrenals, connective tissue, extrathoracic airways, gallbladder, heart wall, kidney, lymphatic nodes, muscle, pancreas, prostate, small intestine wall, spleen, thymus, and uterus. On the other hand, USNRC Part-20 only specifies six tissues required for consideration and an additional five others that receive the highest dose excluding skin and lens of the eye. Based on the principle of ALARA, it is recommended to use the weighting factor recommended

TABLE 9.14 Determination of Human Equivalent Dose in Tissues and Calculation of Whole Body, Committed Effective Dose

Organ/Tissue	R_t for Organs ^a	Equation Used ^b	Human Equivalent Dose (H_t) (mSv)	Weighting Factor (W_T)	Individual Organ Effective Dose ($W_T \cdot H_t$) (mSv)

Sum of weighting factors = 1.0					
Committed effective dose, E (mSv)		17	—		0.822

Abbreviation: NA, not applicable.

^a R_t in Equation 9.16 is the ratio of tissue AUC relative to plasma AUC of ^{14}C , usually from the rat. Human plasma data used in the calculation are not shown.

^b For excretory organs (stomach, lower large intestine, and bladder), the H_t was also calculated by Equation 9.16 for the tissues. As Equation 9.15 for organ content provided a higher, more conservative H_t , this higher H_t value is reported.

^c Dose calculation is based on radioactivity expected to be present in the lumen of the organ.

^d Breast is not sectioned; the fat tissue is alternatively used with the weighting factor for the breast.

^e A weighting factor of 0.025 is applied to ocular uveal tract as its equivalent dose is in excess of the highest dose in any of the twelve organs for which a weighting factor is specified.

in ICRP publication-103 in Tables B-2 and B-3.5. The average radioactive dose for these tissues/organs of the body is used for calculations of effective dose (E) [56] and is given by the following expression:

$$E = \sum W_T \times H_{t(\text{human})} \quad (9.17)$$

where

W_T is the weighting factor for tissue or organ, T

$H_{t(\text{human})}$ is the human equivalent dose in tissue or organ, T .

The calculation of effective dose gives a prospective dose assessment for the planning and optimization of radiation safety and allows a retrospective dose assessment to demonstrate compliance with dose limits or dose constraints in radiological protection.

9.11 EXPERIMENTAL DESIGN OF HUMAN MASS BALANCE STUDIES

With the knowledge on the study designs and the results of the preclinical mass balance studies, the design for human mass balance studies can be appropriately established. Before conducting these studies, an independent institutional review board must approve the study protocol and the written informed consent documents should be obtained from all subjects before the enrollment into the study. The person preparing the dose must be well trained in pharmaceutical handling of the radionuclide, and both nonlabeled drug and radioactively labeled drug should be formulated together in the final dosage form. Both the dosage form and route of administration are recommended to be relevant to the intended use in clinical practice, as determined from the other previous studies. As mentioned previously in preclinical studies, the therapeutic efficacy/purity of the administered dose, including unlabeled and radiolabeled tracers must be determined exactly for the estimation of PK parameters and mass balance recovery parameters. Administration of a radioactive substance to humans should be performed in separate dedicated rooms, and only the qualified study personnel should be allowed with the subject [4]. Coadministration of other supplements such as high fiber diet, mild laxative, or regular fluid intake during the study period to allow sufficient defecation and adequate urination are recommended. In addition, it is advisable to rinse the container after the p.o. administration (if the dosage form is a solution or a suspension and is administered through a container), with suitable solvent to quantify the residual radioactivity [4]. The collection of radioactive biological samples (blood, urine, and feces) for the human studies should be long enough and optimum to allow the estimation of maximum recovery of the radiolabeled compound and its PKs without excessively burdening the patients. The collection interval of blood and urine samples can be designed based on the preclinical and clinical information, such as terminal half-life of the compound; otherwise, it is recommended to take more frequent samples during the distribution phase but less frequent during the terminal elimination phase. The date, time, and weight of the collection container should be recorded, before and after the collection period. Ideally, the collection of excreta should be stopped when all administered radioactivity has been recovered, which is not always the case with human mass balance studies. Assuming the elimination of the drug-related materials (metabolites) is similar to the parent drug, then plasma samples must be taken for at least four terminal half-lives [63], which can be established from previously conducted phase I studies. Under this assumption, 93% of the total radioactivity should be excreted after four half-lives. However, if it is taking more than the expected time to meet the criteria of the radioactivity recovery, then the study completion time may need to extend for more than seven days, sometimes up to 10 days or longer. Under certain circumstances (e.g., too long to hold them in the study center), the subjects under study can be allowed to go back to their homes and asked to bring the excreta (urine and feces) samples to the designated study center to increase the recovery of radioactive dose. For this, it is recommended to determine the levels of radioactivity recovery simultaneously in the collected samples, to get evidence-based extension of collection period. Usually, if there is no stability data available for the study compound and its metabolites in the urine and feces, it is recommended to store all samples at -20°C or less; otherwise, degradation products can mistakenly be identified as metabolites [4]. The sample analysis and the calculation of mass balance and PK parameters are usually performed in the same manner as for preclinical studies

discussed earlier and are summarized in Tables 9.6 and 9.7. It is recommended to calculate these PK parameters for the unchanged drug and its metabolites in human plasma matrix, in place of drug-related total radioactivity, as it composes of unchanged drug and various radioactive metabolites, which will result in pseudo-PK parameters. These total radioactivity-based PK parameters may be used to estimate the absorption in the human body, and after the metabolite profiling, the elimination pathways can be estimated based on the amount of radioactivity recovery in excreta and metabolite profile in each excreta. The contributions of each circulating component (including the parent) are estimated from the ratio of AUC of each component to the AUC of total radioactivity. These metabolites further characterize their contribution toward desired pharmacological and/or toxicological effects as needed.

9.12 CASE EXAMPLE FOR HUMAN MASS BALANCE

9.12.1 Drug B—Mass Balance Study Design

Three healthy, nonsmoking males were chosen from age 20 to 40 years, and a single p.o. dose of 100 mg containing labeled [^{14}C] plus unlabelled drug compound was administered p.o. The p.o. route was chosen because this was the proposed route of administration for human use in the clinical setting. The PKs and disposition of radioactivity in humans were cautiously predicted and the parameters obtained from the preclinical studies were used to calculate the radiation dose for human administration. The radiation doses (equivalent doses) for the individual organs following a single p.o. dose were calculated as described in Section 9.10 and listed in Table 9.14. All the calculations used in this example were based on the ICRP publication-60, and for future studies, as mentioned earlier, readers are advised to follow the revised recommendation from ICRP publication-103 for the calculation of committed effective dose for humans to get a minimum human radioactivity exposure. As shown in Table 9.14, the committed effective dose (human whole-body dose H_{wb}) was calculated to be 0.822 mSv for the radioactive dose of 47 μCi at a drug dose of 100 mg. This predicted effective dose is below the ICRP recommended dose (1 mSv); thus, the radiation health risk of the study volunteers was extremely low.

The radioactive dose given per subject was 47 μCi (1.85 MBq) for the 100-mg dose after calculation. Blood was collected at 0.25, 0.5, 1, 1.5, 2, 3, 4, 6, 8, 12, 16, 24, 36, 48, 72, 96, 120, 144, and 168 h post dose by either direct venipuncture or an indwelling cannula inserted in a forearm vein. Eighteen milliliters of venous blood was collected at each time point in heparinized tubes. Plasma was separated from whole blood by centrifugation, transferred to a screw-top polypropylene tube, and frozen immediately. Urine samples were collected at pre dose and at 0–4, 4–8, 8–12, 12–16, 16–24, 24–36, 36–48, 48–72, 72–96, 96–120, 120–144, and 144–168 h post dose. Feces were collected as passed from time of dosing until at least of 168 h postdose. All these samples were stored at -20°C or less until analysis.

The radioactivity was measured in plasma, blood, urine, and feces by LSC with the same methodology discussed earlier in preclinical studies. The parent drug was measured using a validated LC/MS/MS assay and metabolites were measured semi-quantitatively using HPLC radiodetection with off-line microplate solid scintillation counting and structural characterization by LC/MS.

TABLE 9.15 Pharmacokinetic Parameters After a Single Oral Dose of 100 mg of Drug B in Humans

PK Parameters	Plasma Parent Drug	Plasma Radioactivity	Blood Radioactivity
$C_{\max}$ (ng/mL or ngEq/mL) ^a	397 ± 92	594 ± 153	470 ± 87
$T_{\max}$ (h)	1.1 ± 0.6	2.1 ± 1.3	2.0 ± 1.4
$AUC_{0-\infty}$ (ng · h/mL or ng Eq · h/mL) ^a	1610 ± 460	6000 ± 1610	3850 ± 1580
Apparent $t_{1/2}$ (h)	2.8 ± 1.0	4.6 ± 0.3	5.1 ± 2.5
CL/F (L/h)	65.2 ± 15.5	—	—
V_z/F (L)	269 ± 125	—	—

^aConcentration units are in ng/mL for the intact parent drug and ngEq h/mL for drug-related radioactivity. All values are presented as mean ± SD.

9.12.2 Pharmacokinetics Parameters for Drug B

The PK parameters of drug B were determined by conducting noncompartmental analysis using WinNonlin. The highest concentration in plasma ($C_{\max}$) was achieved at 2.1 h post dose with the mean value of 594 ng Eq/mL (total radioactivity) and 1.1 h post dose with mean value of 397 ng/mL for the intact, unchanged parent drug in all subjects, suggesting rapid gastrointestinal absorption of the drug. The mean plasma concentration–time profiles and other PK parameters of total radioactivity and unchanged drug compound after a single p.o. dose of [¹⁴C] drug are summarized in Table 9.15. The average terminal elimination half-life ($t_{1/2}$) of radioactivity and parent drug was calculated to be 4.6 and 2.8 h, respectively.

9.12.3 Mass Balance Parameters and Interpretations

After a single p.o. administration of 100-mg dose of [¹⁴C] drug B, radioactivity was excreted predominantly in urine (Table 9.16). After 168-h postdose, the excretion in urine and feces averaged 85.4 ± 4.4% and 14.8 ± 3.5% of the administered dose, respectively. The cumulative excretion of radioactivity was complete after 168 h postdose in all subjects averaging 100.2 ± 1.1%, as summarized in Table 9.16. The

TABLE 9.16 Cumulative Excretion of [¹⁴C] Radioactivity in Urine and Feces after Single p.o. dose of 100 mg of Drug B in Humans (Mean ± SD)

Time Period (h)	Urine (% Dose Excreted)	Feces (% Dose Excreted)
0–24	72.7 ± 4.8	1.37 ± 2.0
0–48	81.6 ± 4.2	9.93 ± 8.0
0–72	83.8 ± 4.4	13.2 ± 4.8
0–96	84.7 ± 4.4	14.3 ± 3.7
0–168	85.4 ± 4.4	14.8 ± 3.5
Total (% radioactive dose excreted in urine and feces)	100.2 ± 1.1	

elimination of radioactivity was rapid as more than 90% of the radioactivity was recovered in first 48 h after the dose was administered. Approximately 27% of the drug dosed was excreted as intact, unchanged parent drug (22.5% in urine and 4.54% in feces). The extent of absorption is estimated to be higher than 85.4% (amount of dose recovered in urine) and likely to be even higher since only 4.54% of dose was recovered in feces as unchanged drug. These results were in agreement with the absolute p.o. bioavailability (85%) observed in another clinical study with a single i.v. dose. Since ~22.6% of the dose in urine was recovered as unchanged compound, the renal clearance was estimated to be ~15 L/h.

9.13 CONCLUSIONS

Mass balance studies play an important role in the development of new drugs. These studies give in-depth understanding of absorption, bioavailability, routes (renal, biliary, hepatic, or gastrointestinal), and extent of excretion, metabolite profiling, metabolic pathways, and clearance mechanisms of a drug. The results from these studies aid in designing and conducting renal and hepatic impairment studies, DDI studies, and monitoring the metabolite(s) that may relate to pharmacology or toxicological concerns. The mass balance information will also help in understanding the mechanisms of intersubject variability of the drug exposure and potential DDI in terms of metabolism or transport. Moreover, across species mass balance studies can provide important information on whether a metabolite observed in human is required for separate safety testing in preclinical studies to fulfill the regulatory requirement as stated in the FDA and ICH guidances.

10.1 INTRODUCTION

To provide therapeutic benefit, pharmaceutical agents must gain access to their intended sites of pharmacological effect. Although pharmacologic effect is governed by interactions between drug and molecular targets such as cellular receptors or enzymes, drug transfer from the site of absorption and subsequent distribution to extravascular tissue also contributes to the extent and timing of drug effect. Thus, it follows that the magnitude of effect will generally be related to the amount of drug available to the site of action, whereby insufficient systemic drug levels may result in therapeutic failure and excessive levels could lead to toxicity.

To define safe and effective dosage regimens, an understanding of drug concentrations and their relationship to drug pharmacodynamics (PD) is required. Although some drugs may be administered directly to the site of action, such as by topical, pleural, or peritoneal routes, a majority of drug substances must enter the general circulation and be distributed to tissue before reaching their intended site of action. Therefore, the extent of drug transfer to the general circulation can be a function of drug distribution across successive membrane and cellular barriers. As a dose is transferred between the site of administration and its site of measurement in the circulation, the serial arrangement of physiological membranes and cellular elements may lead to cumulative drug loss. Thus, bioavailability is the pharmacokinetic (PK) parameter that describes the proportion of a dose to successfully reach the bloodstream as parent drug [1].

Bioavailability studies are largely concerned with determining systemic drug availability after oral administration, as the oral route is the intended mode of administration for the majority of drug substances. However, absorption of an oral dosage form is a complex process that is influenced by gastrointestinal (GI) physiology as well as the physicochemical properties of a drug. Following oral administration, drug must pass

from the GI lumen, across the gut wall, and into the hepatic circulation before systemic distribution. In addition to GI physiology, transfer of an oral dose to the systemic circulation also depends on drug solubility in aqueous and lipid environments as well as the potential for recognition by membrane transporters and metabolizing enzymes. From a PK perspective, bioavailability studies relate systemic exposure to drug absorption, while helping to understand mechanisms underlying drug distribution, transport, and metabolism.

Bioavailability studies are also conducted to evaluate the performance of one or more drugs or drug products against a previously defined reference. Such studies are referred to as *comparative bioavailability* studies and are designed to demonstrate bioequivalence of test and reference formulations for both new drug as well as generic drug products. While comparative studies are important elements of drug development, they may also be conducted after drug product registration in support of manufacturing changes [2]. Early in the drug development process, oral bioavailability of an initial dosage form might be determined relative to drug administered by the intravenous (IV) route or relative to an oral solution. As drug development progresses toward registration, improvements in oral delivery frequently lead to formulation changes and comparative bioavailability studies may be required in order to confirm equivalent PK and reestablish drug safety and efficacy of the reformulated dosage form relative to the earlier form. For marketed drug products, studies to demonstrate bioequivalence could be necessary following major changes in components, composition, and/or method of manufacture made after approval.

Determining bioequivalence is also a critical component for abbreviated new drug application (ANDA) submissions of generic drug products. Approval of generic drug products relies on the bioequivalence between the generic and innovator formulations. In order to be considered bioequivalent, drug products must contain the same active ingredient and display comparable bioavailability when studied under similar experimental conditions [3]. Thus, it is assumed that two bioequivalent drug products will be therapeutically equivalent and may be substituted for one another.

This chapter provides an introduction to the interrelated concepts of bioavailability and bioequivalence and their application to characterize drug disposition. While calculating bioavailability provides an assessment of the amount of drug reaching the systemic circulation relative to a reference dose, demonstration of bioequivalence for two drug formulations further permits an important assumption of therapeutic equivalence and potential for product substitution in clinical practice. As drug products are frequently designed for administration by the oral route, potential sources of drug loss that could contribute to incomplete oral bioavailability are also reviewed.

10.2 BIOAVAILABILITY

Bioavailability is characterized by the rate of drug absorption, how fast a drug enters the systemic circulation, and its extent of absorption, the quantity of dose to enter the body. These essential features of a nonvascular dosage form define the time course of circulating drug concentrations and their relationship to therapeutic effect, where the onset of drug effect is often a function of absorption rate and effect duration is typically related to the extent of absorption. Thus, the PK parameter bioavailability is

used to describe the proportion of a dose transferred to the site of drug measurement that becomes available for tissue distribution.

In experimental terms, drug bioavailability is determined by comparing the exposure levels of intact drug of a test dose to the exposure levels of a reference dose. When the entire reference dose is available at the site of sampling, as assumed for drugs administered by the IV route, then the systemic availability of a test dose is referred to as *absolute bioavailability*.

Drug concentrations are commonly measured in venous blood or plasma and therefore intravenously administered drugs are considered to be completely available within the systemic circulation. Although this is a valid assumption when intact drug reaches the arterial bloodstream without loss, experimental verification of the assignment of 100% bioavailability is not common. On IV administration, the entire dose becomes available to the pulmonary circulation during exchange to the arterial blood supply. While contributions to first-pass metabolism by the lung are difficult to quantify, the activities of several cytochrome P450 (CYP) enzymes are present in human lung [4,5]. In addition, recent evidence suggests that CYP activities localized in the right ventricle of the human heart may also play a role in pulmonary first pass [6]. Although the potential for pulmonary first-pass extraction exists for an IV dose, equivalent extraction is assumed for an oral dose during exchange to the arterial blood supply before sampling and therefore the net effect on estimating bioavailability is thought to be negligible.

Frequently, however, drug administration by the IV route cannot be considered, as the majority of drugs are not approved for IV use nor have they been monitored in a clinical development setting following IV administration. In order to evaluate human IV PK for absolute bioavailability determination, supportive toxicology and manufacturing data are also required to demonstrate drug safety associated with IV dosing. Additionally, dosing formulations developed for a nonvascular route may not be suitable for human IV use and thus identification of a formulation compatible with IV administration may also be required. Although the study of human PK following IV administration would generate valuable exposure data for future bioavailability characterization, approval to conduct clinical PK studies is not always sought.

When IV dosing is not plausible, both the reference dose and test dose of the same drug substance are introduced by nonvascular route(s) of administration. Consequently, systemic exposure following a test dose will be compared to a reference dose for which complete availability at the site of measurement cannot be assumed. The parameter *relative bioavailability* is used to characterize the availability of a test dose relative to a nonvascular reference dose.

Bioavailability studies to compare drug formulations dosed by nonvascular routes of administration are frequently undertaken to demonstrate generic drug bioequivalence to an innovator reference formulation. The calculation of relative bioavailability may also contribute to understand exposure–effect relationships for drug products when measurements of drug levels occur directly at the site of action. For instance, concentrations of the anticancer agent temozolomide were determined in brain interstitium by intracerebral microdialysis after oral temozolomide administration. Using this approach, temozolomide bioavailability within the central nervous system was determined to be 17.8% relative to systemic temozolomide concentrations after oral dosing [7]. Similarly, external γ -scintigraphy was used to determine relative bioavailability directly at a local site of drug action following nasal spray application of cromolyn sodium [8]. Although these specialized techniques for drug monitoring are not routine

approaches to determine drug bioavailability, knowledge of drug disposition at the site of therapeutic activity may further provide an understanding of exposure–effect relationships.

In other cases, however, alternate routes have been employed to facilitate drug application directly to the site of action when drug loss that may occur after oral dosing has not supported clinical use or when systemic exposure is to be minimized by design. Nonoral drug administration by topical [9], inhalation [10,11], and intranasal [12] routes are common. However, comparative bioavailability studies based on systemic exposure are not always possible. For instance, dermatological agents administered by topical application to the skin effectively maximize drug concentration at the site of action with minimal drug present in circulation. Consequently, systemic availability does not necessarily reflect local tissue exposure. Comparisons of drug formulations for bioequivalence determinations have instead utilized measures of *in vivo* tissue exposure such as tape stripping and microdialysis [9,13]. Recent efforts have also attempted to relate measures of *in vitro* permeability from an excised human skin model for *in vivo* efficacy predictions [14].

10.2.1 Calculation of Absolute Bioavailability

Following oral dose administration, maximum plasma concentration of drug ($C_{\max}$) is commonly used to evaluate the rate of absorption, while total area under the plasma concentration versus time curve (AUC) is used to evaluate the extent of absorption. However, in terms of estimating drug bioavailability, the proportion of dose reaching the systemic circulation as intact drug is determined by comparison of AUC exposures. When plasma drug concentrations are compared after administration of an extravascular test dose and IV reference dose, absolute bioavailability (F) is calculated as the AUC ratio of extravascular (AUC_{ev}) and IV (AUC_{iv}) exposures. As the IV route of administration is assumed to result in complete systemic drug availability, reference to AUC_{iv} provides an estimate of absolute bioavailability. Often the occurrence of high initial drug concentrations after IV dosing precludes evaluation of a matched dose by a nonvascular route. Accordingly, dose levels are taken into account when calculating absolute bioavailability [1]:

$$F = \frac{AUC_{\text{ev}}}{AUC_{\text{iv}}} \times \frac{(\text{Dose})_{\text{iv}}}{(\text{Dose})_{\text{ev}}} \quad (10.1)$$

Bioavailability may also be calculated from urinary excretion data for drugs that undergo renal elimination. When renal clearance accounts for the same proportion of total drug clearance after IV and extravascular administrations, absolute bioavailability can be estimated from urinary excretion data. This approach is feasible as the fraction of drug excreted unchanged in urine is independent of the route of administration within a linear dose range. However, a requirement for this approach is the complete collection of dose excreted in urine. Thus, by comparing the total amount of unchanged drug excreted in urine (Au_{inf}) after extravascular and IV dosing, the fraction of extravascular dose available in the systemic circulation can be determined by

$$F = \frac{(Au_{\text{inf}})_{\text{ev}}}{(Au_{\text{inf}})_{\text{iv}}} \times \frac{(\text{Dose})_{\text{iv}}}{(\text{Dose})_{\text{ev}}} \quad (10.2)$$

Inherent in Equations 10.1 and 10.2 is the assumption that drug clearance remains constant and independent of the route of administration. Clearance of drug from the systemic circulation is defined by the rate of drug elimination and drug concentration in plasma [15]. Therefore, in terms of mass balance, systemic clearance (CL) may be expressed as a ratio of amount of bioavailable dose and total AUC exposure in plasma such that

$$CL = \frac{F \times \text{Dose}}{AUC} \quad (10.3)$$

Equation 10.3 can be simplified for an IV dosing situation when complete bioavailability is assumed (i.e., $F = 1$). Thus, expressing an AUC ratio following extravascular and IV administrations in terms of bioavailable dose and systemic clearance, it follows that absolute bioavailability may be calculated by the following:

$$F = \frac{AUC_{ev}}{AUC_{iv}} \times \frac{CL_{ev}}{CL_{iv}} \times \frac{(\text{Dose})_{iv}}{(\text{Dose})_{ev}} \quad (10.4)$$

When the assumption of constant clearance holds after IV and PO dosing, Equation 10.4 may be simplified to Equation 10.1.

When plasma drug levels fall below the lower limit of assay quantitation soon after dose administration, insufficient concentration–time data may lead to unreliable estimates of AUC exposure and inaccurate bioavailability determinations. In such cases, parent drug bioavailability could be determined indirectly by monitoring metabolites present in circulation. Accordingly, determinations of plasma metabolite AUC (AUC_m) after extravascular and IV dosing can be used to calculate parent drug bioavailability when presystemic first-pass metabolism does not play a role in metabolite formation [16]:

$$F = \frac{AUC_{m,ev}}{AUC_{m,iv}} \times \frac{(\text{Dose})_{iv}}{(\text{Dose})_{ev}} \quad (10.5)$$

10.2.2 Variability in Bioavailability Estimates

Variation in oral bioavailability may arise from potential differences in drug absorption or first-pass elimination from the gut and liver across a patient population. However, it is generally accepted that variability will be greatest for drugs characterized by low bioavailability due to high first-pass extraction [17]. Accordingly, when variability in drug PK among individuals is large, predictions of PD effect at a given dose level are met with uncertainty. Moreover, PK variability between individuals is of particular concern for drugs with a narrow therapeutic index, as relatively small differences exist in drug concentrations associated with PD effect and toxicity or therapeutic failure.

Individual differences in drug PK can arise from physical differences in age, sex, and body size as well as disease state. In addition, there is increasing evidence that genetic differences in enzyme and transporter activities and expression also contribute to PK variability. In some cases, such as for anticancer agents, attempts to individualize treatment have involved calculating dose in terms of body surface area. Alternatively, bioavailability studies conducted in healthy subjects commonly employ a crossover design within the same group of individuals to minimize potential sources of PK

variability. This testing paradigm ensures all treatments evaluated in the study can be compared for each individual across the same panel of subjects. Thus, a crossover design avoids potential bias in comparisons of AUC exposure and decreases the effects of variability in drug elimination between subjects (intersubject). However, crossover studies do not account for PK variability within the same individual (intrasubject). Differences exhibited in systemic clearance within the same individual from one dose administration to the next can be difficult to distinguish experimentally and effects on bioavailability cannot readily be predicted.

Although identification of intrasubject differences in clearance would reduce variability in the estimation of bioavailability, determination of clearance differences in the same individual from one treatment to another is not possible using routine approaches without assumptions regarding other PK parameters. However, changes in elimination half-life ($t_{1/2}$) are measurable and may reflect changes in clearance when apparent volume of distribution is assumed to be constant between dose administrations. Expressing clearance in terms of elimination half-life and volume of distribution ($CL = 0.693 \times V_d/t_{1/2}$) and substituting into Equation 10.4 yields

$$F = \frac{AUC_{ev}}{AUC_{iv}} \times \frac{t_{1/2,iv}}{t_{1/2,ev}} \times \frac{(Dose)_{iv}}{(Dose)_{ev}} \quad (10.6)$$

Thus, in some circumstances, the accuracy of bioavailability estimates may be improved by incorporating half-life estimates to accommodate changes in clearance. However, experimentally derived estimates of half-life are a subjective measure of drug elimination that can be confounded by multiphasic concentration–time profiles as well as relatively slow rates of drug absorption that cannot be distinguished from the rate elimination.

The use of stable isotope methodologies provides an additional approach to decrease potential sources of variability in the calculation of bioavailability. To address potential within-subject differences in drug clearance that may arise from dosing on two separate occasions, stable labeled and nonlabeled drug have been administered simultaneously by two different dosing routes or by the same dosing route as two different formulations. These studies use drug substances prepared by incorporation of stable isotopes in order to take advantage of mass spectrometric analytical methods to distinguish between different isotopic forms of the drug in the same sample. Drug bioavailability studies have commonly employed the stable isotopes of hydrogen (deuterium, [2H]), carbon (carbon-13, [^{13}C]), and nitrogen (nitrogen-15, [^{15}N]). In this way, human PK for two simultaneous dose administrations can be determined from concentrations of stable labeled and nonlabeled drug quantified from the same plasma samples. Implicit to an assumption of similar PK is an expectation that both isotopically labeled and nonlabeled drug substances will distribute identically in the systemic circulation and be metabolized identically.

Stable isotope techniques have been used to determine the absolute oral bioavailability of many drugs, including ribavirin, an antiviral agent, the calcium channel blocker verapamil, and the anticonvulsant phenytoin. In the case of ribavirin, prolonged systemic exposure caused by intracellular sequestration of drug would require a long washout period between ribavirin dosing. A stable isotope study was planned with ribavirin in order to avoid the risk of insufficient washout between the treatment phases of a crossover design. To estimate absolute bioavailability, the study design involved

IV administration of [^{13}C]-ribavirin followed 1 h later by an oral dose of unlabeled drug [18]. The use of stable isotope methodology provided a robust estimate of ribavirin bioavailability (51.8%) without a period bias or a washout effect to confound the data. The absolute oral bioavailability of verapamil was also investigated using isotopically labeled drug. Deuterium-labeled verapamil was dosed orally to compare first-pass metabolism differences in patients with liver cirrhosis and healthy subjects. Dosage adjustments for patients with liver disease were recommended as a result of a nearly twofold increase in bioavailability associated with a reduction in oral clearance [19]. A stable isotope approach was also employed to estimate absolute bioavailability of phenytoin in patients with epilepsy. Conventional approaches to determine bioavailability are complicated by the slow absorption rate, extensive plasma protein binding, nonlinear PK, and narrow therapeutic window of phenytoin. Mean estimates of absolute bioavailability after simultaneous administration of an oral formulation and parenteral stable labeled phenytoin ranged from 86.4% in younger patients to 92.5% in older patients [20].

The use of stable isotopes has also facilitated relative bioavailability determinations in order to establish the bioequivalence of highly variable drugs. The oral bioavailability of the anti-arrhythmic moricizine was studied by simultaneous administration of nonlabeled tablet and [^{13}C]-moricizine oral solution. Initial studies determined that high variability within subjects due to the extensive first-pass metabolism of moricizine precluded a conventional crossover study design. It was estimated that a large number of study subjects would be required for a crossover study in order to pass average equivalence criteria with the desired statistical power. Instead, fewer subjects were studied by a stable isotope approach in order to confirm the bioequivalence of a moricizine oral solution to the marketed commercial tablet [21].

Although the use of stable label techniques for the study of bioavailability has afforded opportunities to minimize variability within subjects, inherent limitations regarding use in human studies have curtailed the broad application of this approach. Stable isotope use in evaluating bioavailability has been limited by requirements for custom syntheses of highly purified material conducted in accordance with good manufacturing practices (GMP), challenges associated with preparation of stable labeled formulations that are representative of clinical formulations and the need for a complement of nonclinical safety studies necessary to gain approval for IV dosing of stable labeled drug.

Advances in mass spectrometry have provided new opportunities for determining drug bioavailability with the use of trace levels of radioactive isotopes, obviating some of the drawbacks associated with the use of stable label approaches outlined above. Accelerator mass spectrometry (AMS) is a relatively new technique with high sensitivity, used to measure low concentrations of radiolabeled drug and metabolites in multiple matrices. The analytical sensitivity of AMS is derived from the fact that individual drug molecules are being detected by the mass spectrometer. Conventional radiolabel studies rely on detection methods such as scintillation counting to monitor the radioactive decay of the labeled drug. In contrast, AMS measures the ratio of individual radioactive atoms, commonly carbon-14 for human studies, and the naturally abundant carbon-12 atoms in samples after drug administration. A comparison of carbon-14/carbon-12 ratios in samples collected from subjects who received drug versus the same ratio in pretreatment samples allows very low levels of drug to be quantified in the femtomole to attomole concentration range.

The high sensitivity of AMS has made this technology amenable to mass balance studies and microdose scale PK studies [22,23]. Human bioavailability studies have also employed AMS technology to monitor low circulating plasma concentrations following subtherapeutic amounts of radiolabeled drug. Study designs to assess absolute bioavailability have involved either simultaneous IV administration of a microdose of radiolabeled drug with oral administration of nonlabeled drug or administration of a microdose of radiolabeled drug on two occasions separated by a suitable washout period between IV and extravascular dosing.

Although microdose studies represent an efficient approach to estimate absolute bioavailability in the clinic and are supported by an abbreviated safety dossier, drug PK after a microdose must accurately represent the kinetics at higher therapeutic dose levels. Accurate bioavailability determinations require that the PK are independent of drug concentrations across a range of dose levels. Therefore, studies have occasionally been conducted in nonclinical species to confirm linear PK at microdose and therapeutic dose levels before dosing to human subjects [24,25].

The bioavailabilities of several drugs following microdose administrations have also been conducted in human subjects in order to evaluate microdosing study designs. Results from a study in human volunteers indicated concordance between subtherapeutic and therapeutic dose PK for erythromycin, midazolam, and an experimental compound ZX253 [26]. Estimates of absolute bioavailability were determined for each compound by simultaneous administration of an IV carbon-14-labeled microdose plus a pharmacological oral dose and compared with estimates obtained in a conventional crossover study at therapeutic dose levels. Results of the study indicated relatively good agreement (i.e., differing by less than twofold) in the estimates of bioavailability obtained from microdose and conventional studies for midazolam and ZX253. The estimate of erythromycin bioavailability from a conventional crossover study at therapeutic dose levels was greater than twofold larger than the estimate of bioavailability obtained from a microdose—pharmacologic dose paring (35% vs 14%, respectively). However, the difference in absolute bioavailability was attributed in part to the acidic conditions of the upper GI tract and potential degradation of erythromycin following oral administration.

10.3 BIOEQUIVALENCE

The assessment of bioequivalence of two or more drug products offers important information regarding the safe and efficacious use of therapeutic agents. When measures of systemic exposure relate to drug efficacy and safety, bioequivalence confers therapeutic equivalence. As such, a common goal of all bioequivalence studies is to demonstrate that one drug product can be substituted for a second.

Studies to test for bioequivalence involve comparisons of bioavailability between two drug formulations that are either pharmaceutical equivalents or pharmaceutical alternatives of one another. That is, drug products that contain the same active ingredient and administered in the same dosage form (pharmaceutical equivalents) or in similar dosage forms prepared for the same route of administration (pharmaceutical alternatives). For pharmaceutical equivalents or alternatives to be considered bioequivalent, the active ingredient in a test product must not exhibit a significantly different rate and extent of absorption as that of the reference product when administered at the same

molar dose and under similar experimental conditions [3]. Inherent in the definition of bioequivalence is an assumption that once absorbed into the circulation, distribution, metabolism, and excretion of the active ingredient will be the same irrespective of formulation.

Two drug products are considered to be therapeutically equivalent if they are pharmaceutical equivalents and bioequivalent, thus leading to the same profile of clinical efficacy and safety. However, if test product levels in plasma are substantially lower than those of the reference product, concerns of a potential lack of therapeutic efficacy are raised. Alternatively, when test product levels are higher than those of the reference then concerns shift to a focus on safety. Although therapeutic equivalence is generally not tested directly, it is presumed based on tests of bioequivalence. When bioequivalent drug formulations share the same clinical effect and safety profile in patients, then they are considered to be therapeutically equivalent and may be used interchangeably.

Bioequivalence studies can be integral to the development of new drugs, as improvements in drug formulation may be required during clinical development. For instance, drug formulations used in clinical trials are often not suitable for commercialization. Thus, demonstrating bioequivalence of a drug product intended for market use will allow its substitution for the experimental formulation. Bioequivalence trials are also conducted to evaluate the effects of food, changes in the marketed formulation, or dose route of administration. Recent efforts to reformulate the antifungal agent amphotericin B represent attempts to reposition a previously approved drug that suffers from infusion-related side effects and renal toxicity. Amphotericin B has low solubility and permeability that result in negligible oral absorption. Reformulation of amphotericin B for oral administration would significantly lower treatment costs and improve its accessibility [27]. In contrast to oral formulations, therapeutic equivalence of drug products formulated for IV administration may be established by demonstrating pharmaceutical equivalence and does not require *in vivo* testing [28].

Bioequivalence studies are also conducted as components of an ANDA for a generic drug product. Because generic drugs are intended to be interchanged with innovator products, a demonstration of bioequivalence between formulations is essential for safe and efficacious use of the generic formulation. Thus, therapeutic equivalence to the innovator drug product is accepted on demonstration of bioequivalence of a pharmaceutically equivalent generic drug product.

The rules that govern generic drug substitution were defined by the Drug Price Competition and Patent Term Restoration Act of 1984 (Hatch–Waxman Amendments). Since adopting Hatch–Waxman, more than 11,000 generic drug products have been approved by the Food and Drug Administration (FDA). In order to judge the relative success of these approvals, a recent survey was conducted by FDA of generic drugs approved over a 12-year period spanning from 1996 to 2007 [2]. The survey revealed that in 2070 bioequivalence trials conducted over a 12-year period through 2007, the average difference in rate and extent of drug absorption between generic and innovator products was 4.35% and 3.56%, respectively [2].

In order to avoid complications that could arise from product substitution, the FDA maintains a list of generic drugs that can be safely and appropriately substituted for brand products. These drugs are listed in a federal publication entitled *Approved Drug Products with Therapeutic Equivalence Evaluations*, commonly known as the *Orange Book* [29]. To permit substitution of a brand drug, a generic equivalent must demonstrate bioequivalence as part of the approval process. However, the process by which a

brand drug is approved differs from the process required for generic product approval. A summary of the similarities and differences between new drug application (NDA) and ANDA dossiers are shown in Table 10.1. Both innovator and generic products must contain the same active ingredient in the same strength. Moreover, drug chemistry, manufacturing details and quality control measures must be documented for both products. However, after this point, the two processes begin to diverge. The Hatch–Waxman Amendments do not require generic drug applicants submitting an ANDA to provide nonclinical or clinical studies to establish the safety and efficacy of the active ingredient, as these characterizations have been established previously for the innovator product. Required of the generic product is demonstration of bioequivalence to the innovator product.

10.3.1 Study Design

Bioequivalence studies are generally conducted in a small number of healthy volunteers to determine the relative bioavailability of one or more test formulations following single dose administration. In most studies, the reference formulation is defined as the historical or innovator drug product and all individuals participating in the trial typically receive reference as well as test formulations. There are three basic study designs employed for determination of drug product bioequivalence—randomized crossover design, parallel design, and partial-block crossover design.

10.3.1.1 Randomized Crossover Design. A two-period randomized crossover design is one of the most commonly employed study designs to test the equivalence of two treatments. In accordance with this design, subjects are divided into two equal groups on random assignment to either a test or reference treatment group. After the first dosing period, a sufficient washout period equivalent to five or more drug half-lives is allowed to elapse before dosing resumes. For the second dosing period, subjects are crossed over into the opposite treatment group and receive either the test or reference dose depending on their dosing history in the first period. A randomized crossover study is intended to minimize intersubject variability by employing a Latin square design to allow each individual serves as a control subject. Bioequivalence studies to assess multiple regulatory requirements might employ a randomized

crossover of multiple treatments with a Latin square design. For instance, a study to compare test and reference treatments in fed and fasted subjects would generally be conducted as a single dose, randomized, four-period crossover design.

10.3.1.2 Parallel-Group Design. In a parallel study, subjects are divided into equal groups on random assignment to either a test or reference treatment group. Subjects receive the assigned treatment during the study and plasma concentrations are measured. A comparison of results allows an assessment of relative bioavailability. In contrast to the crossover design, higher intersubject variability is anticipated with a parallel design and larger numbers of enrolled subjects will be required. Consequently, testing for formulation differences could be insensitive due to a potential for larger statistical error. However, in some circumstances, a parallel-group study design may be a preferred option. For instance, parallel-group studies might be used to evaluate the therapeutic equivalence of two formulations in patients if treatment changes during the course of the study are precluded by consideration of patient welfare [31,32]. In addition, parallel designs might also be preferred for studying drugs with long half-lives or those requiring lengthy follow-up periods, thus making crossover designs impractical options.

10.3.1.3 Partial-Block Crossover Design. A partial-block design is an extension of the crossover design concept in which subjects receive a subset of formulations being tested. This design might be considered when a comparison of several formulations is planned for each subject in a time-consuming trial that potentially risks high numbers of subject dropouts. A partial-block crossover design could also be employed when studying a long half-life drug. For drugs with a long half-life, an extended duration of a washout period between treatment arms could potentially add several weeks to a complete crossover trial. Using a partial-block crossover design, each subject would experience fewer treatment washout periods, while maintaining within-subject comparisons that are intended to minimize variability. In general, the number of individuals enrolled in a partial crossover study is less than what is required for a parallel design but greater than that required for a complete crossover design.

As an example, a partial-block crossover design was employed to study the 5- α -reductase inhibitor dutasteride in a combination capsule with the α_1 -adrenoceptor antagonist tamsulosin due to the markedly different half-lives of these two compounds [33]. Dutasteride has a half-life of 7–9 days, much longer than the 9–11 h for tamsulosin, which required at least 28 days of washout between treatment periods. If conducted as a single four-way crossover study, the three long washout periods would have resulted in an excessively long study of approximately five months in duration. To avoid lengthy washout periods, a three-way partial crossover design was selected to evaluate two formulations in fed (groups A and B) and fasted (groups C and D) healthy volunteers, shown in Table 10.2. This design attempted to minimize the time spent on study for the subjects, while maintaining within-subject comparisons.

10.3.2 Statistics

The number of individuals enrolled in a bioequivalence study will be determined by the PK variability of the reference dose and based on prior experience. In general, the study size must be sufficient to detect a 20% difference in the measured exposure parameters

with 80% certainty. The dose selected for study is often the highest strength being considered, as comparisons are most discriminating between treatments when exposures increase proportionally or greater than proportional to changes in dose level. When exposure increases are less than dose proportional, the lowest strength dose should be compared [2].

Data resulting from bioequivalence studies are evaluated statistically to analyze two one-sided confidence intervals. The first of two one-sided tests determines if a test product is 20% less bioavailable when substituted for the reference. A second test determines whether the reference is 20% less bioavailable when substituted for the test product. A difference of more than 20% for each of the statistical tests is considered significant, resulting in a lack of bioequivalence. In the case of the two one-sided tests, the null hypothesis is one of nonequivalence. Thus, incorrectly concluding bioequivalence for two nonequivalent drug products (type I error) places risk on the consumer. Alternatively, an incorrect conclusion of bioinequivalence for two equivalent drug products (type II error) places risk on the sponsor.

In practice, the two one-sided tests are each carried out at a 0.05 level of significance, with the combined tests yielding a 10% total error and 90% confidence interval of 80–125%. Therefore, the bioequivalence of two drug preparations can be concluded when the 90% confidence intervals of the geometric mean test/reference ratios of $C_{\max}$ and AUC fall within the limits of 80–125%. In other words, bioequivalence will be concluded when the test product differs from the reference product by $-20\%/+25\%$ or less in terms of the rate and extent absorption. Use of the $-20\%/+25\%$ interval was based on a medical decision that differences in systemic drug concentrations that fall within the $-20\%/+25\%$ range would not likely be clinically significant [34].

10.3.3 Approaches to Demonstrate Bioequivalence

Bioequivalence studies are designed to determine whether a test formulation may be substituted for an existing reference formulation. Successful substitution requires that the two drug products will provide equivalent therapeutic effects. For two oral drug products to be considered bioequivalent, each product must exhibit the same rate and extent of absorption. Thus, bioavailability must be measured by appropriate *in vivo* or *in vitro* methods in order to document bioequivalency. In accordance with accepted FDA methods, studies to determine the bioequivalence of two drug products may be conducted with PK, PD, clinical, or *in vitro* endpoints [3]. Thus, experimental methods to demonstrate bioequivalence will vary case by case, as the selection of appropriate study design and outcome measures will depend on the characteristics of drug products to be compared.

10.3.3.1 Pharmacokinetic Studies. Studies to quantify systemic exposure and characterize drug PK provide opportunities to compare drug bioavailability. Inherent to these studies is the assumption that systemic exposures will reflect drug concentrations at the site of action and thus will provide some assurance of comparable therapeutic effects. For orally administered drugs, the parameters of $C_{\max}$ and AUC provide measures related to the rate and extent of drug absorption, respectively. Bioequivalence studies commonly enroll healthy volunteers to receive a single dose of each formulation. A crossover study design is employed in order to minimize interindividual variability influences on bioavailability, as exposure measurements are assumed to have less interoccasion variability compared to the variability associated with formulation performance [3]. Differences in bioavailability will therefore likely reflect true differences in formulation.

Establishing bioequivalence is most often based on parent drug concentrations, as the parent compound is generally the entity most sensitive to formulation differences. However, when safety or efficacy is considered a function of all drug-related species present in circulation, then monitoring metabolite plasma concentrations to determine the bioequivalence of two drug products could be warranted. Metabolite exposure might be appropriate to monitor if parent drug is rapidly and extensively metabolized, pharmacological activity is correlated with metabolite levels, or if both parent drug and metabolite account for therapeutic effect [35].

Circulating levels of pharmacologically active metabolites are frequently monitored in comparative studies in order to estimate the relative bioavailability between formulations of high clearance drugs. For example, the anthelmintic agent albendazole undergoes rapid and essentially complete first-pass metabolism to a sulfoxide metabolite. Suspension and solution formulations were found to provide 4.3- and 9.7-fold improvements in oral bioavailability relative to tablets, respectively, as demonstrated by comparing AUC exposures of the sulfoxide metabolite [36]. Similarly, the potent desmethyl metabolite of tramadol, a centrally acting analgesic, was monitored to compare the PK of an extended-release tablet relative to an immediate-release reference product [37]. However, in the case of the antiplatelet agent clopidogrel, neither parent drug nor pharmacologically active metabolite is present in circulation at high concentrations following oral administration. Therefore, circulating levels of an inactive carboxylic acid metabolite of clopidogrel were monitored to compare different formulations in a randomized crossover study [38,39].

10.3.3.2 Pharmacodynamic Studies. PD studies are designed to establish bioequivalence of drug products based on measures of pharmacological effect. PD studies differ from PK studies in that circulating drug levels may or may not reflect concentrations at the site of action or correlate with therapeutic effect. PD endpoints are used to determine bioequivalence more often for drug products applied directly to the site of action where they may exert their desired effect, such as topical cream formulations [40,41]. In such cases, drug products are not intended to be absorbed into the systemic circulation. Therefore, bioavailability may be assessed by measurements intended to reflect the rate and extent to which drug becomes available at the site of action. Frequently, however, PD measurements are obtained in conjunction with PK measures in order to relate circulating drug concentrations with drug effect. Thus, the bioequivalence of drug products would typically be based on a measure of dose–response equivalence, where an $E_{\max}$ model is commonly assumed. Drug product comparisons might be made in terms of maximal effect, minimal effect, or average effect measures as well as the area under the effect versus time curve (AUEC). When PK data are available, drug concentrations associated with half-maximal effect (EC_{50}) may be compared when calculated from the model:

$$E = \frac{E_{\max} \cdot C}{EC_{50} + C} \quad (10.7)$$

where E is the effect and $E_{\max}$ the maximal effect [39,42].

10.3.3.3 Clinical Studies. Bioequivalence may also be based on a comparison of clinical outcomes between treatment groups. However, clinical assessments are generally not the sole determinant of equivalence when plasma drug concentrations or measures of PD effect are also available. Although clinical endpoints may be useful to conclude bioequivalence when quantitative measurements are not feasible, clinical assessments are also subjective and difficult to reproduce. Additionally, clinical studies frequently require large numbers of patients in order to ensure adequate statistical power to differentiate drug products.

Most clinical endpoint bioequivalence studies are limited to determination of whether a given treatment failed or succeeded. In a recent trial with the atypical antipsychotic clozapine, a subgroup of patients was randomly assigned to switch to a generic formulation or remain on the initial formulation. Both patient groups were monitored in parallel during the study and clinical outcomes determined from psychiatric tests administered before the switch and at time points after the switch were compared across treatments. A lack of significant differences in score results between the two treatment groups allowed investigators to conclude bioequivalence of generic clozapine based on therapeutic equivalence [31]. Clinical endpoints were similarly used to test the bioequivalence of two formulations of the antifungal agent amphotericin B. On the basis of comparison of clinical cure rates in patients with visceral leishmaniasis treated with each formulation, therapeutic equivalence of the test liposomal formulation of amphotericin B was concluded. In the trial, a single infusion of liposomal amphotericin B was determined to be noninferior to conventional therapy with amphotericin B deoxycholate [32].

10.3.3.4 In Vitro Studies. A fourth approach to characterize drug formulation bioequivalence incorporates knowledge of the key determinants of oral absorption. The biopharmaceutical classification system (BCS) provides a scientific approach to classify drug substances based on *in vitro* measurements of aqueous solubility and intestinal permeability [43]. Using BCS, drugs may be categorized into four classes according to *in vitro* estimates of aqueous solubility and permeability to predict *in vivo* bioavailability, as shown in Fig. 10.1. On the basis of this classification scheme, high solubility drugs may be characterized as having either high permeability (class I) or low permeability (class III), and low solubility drugs are similarly characterized as either high (class II) or low (class IV) permeability. Subsequently, BCS classification was adopted by FDA to allow waiver of *in vivo* bioavailability and bioequivalence testing of immediate-release solid dosage forms for drugs characterized by high solubility and high permeability (class I) that exhibit rapid dissolution [44]. Thus, characterization of drugs in terms of the fundamental properties governing oral absorption seeks to ensure similarities in systemic availability.

The utility of the BCS to classify drugs in terms of solubility and permeability has also provided a framework to predict the effects of food on oral absorption [46]. Physiological changes induced by the presence of food in the GI tract were predicted to similarly influence the oral absorption of drugs of the same BCS class. A relationship between drug disposition and BCS classification was later recognized, as drug substances characterized by high permeability (classes I and II) were eliminated primarily by metabolism and low permeability compounds (classes III and IV) were primarily excreted in urine and bile. On the basis of these observations, a modification was proposed to replace the permeability criterion of BCS with a designation of the major route of drug elimination [45]. Hence, the biopharmaceutics drug disposition classification system (BDDCS) was proposed with metabolism as an alternate measure of drug permeability (Fig. 10.1). BDDCS has also been used to predict the mechanistic effects of food on drug absorption [47].

In general, the *in vitro* determination of aqueous solubility is relatively straightforward and has led to accurate characterization of most drugs. As such, waiver of *in vivo* bioavailability and bioequivalence testing of rapidly dissolving drugs belonging to BCS class I is well accepted. A similar waiver for drugs belonging to BCS class III (high solubility and low permeability) that exhibit rapid dissolution has also been proposed [48,49]. However, *in vitro* predictions of intestinal drug permeability do not share the same level of consensus as do measures of aqueous solubility. This has led to increased acceptance of alternatives to the BCS measures of permeability, such as the

BCS		BDDCS	
Class 1 High permeability High solubility	Class 2 High permeability Low solubility	Class 1 High metabolism High solubility	Class 2 High metabolism Low solubility
Class 3 Low permeability High solubility	Class 4 Low permeability Low solubility	Class 3 Low metabolism High solubility	Class 4 Low metabolism Low solubility

Figure 10.1 Comparison of biopharmaceutics classification system (BCS) and biopharmaceutics drug disposition classification system (BDDCS). *Source:* Refs. 43 and 45.

incorporation of drug elimination by the BDDCS [45,50]. Although contrasting features of the BCS and BDDCS suggest differences in predictions of *in vivo* absorption should be anticipated, a recent comparison of drug classifications indicated that the two systems were largely in agreement. Concordance in the BCS and BDDCS classification of drugs with low solubility (classes 2 and 4) was observed with 87–92% agreement across 164 compounds. The level of concordance was slightly lower for high solubility drugs (classes 1 and 3) ranging from 64% to 72% being identically classified. The distinguishing feature leading to differences between the two systems was the selection of the BCS permeability reference drug. Overall agreement between BCS and BDDCS predictions was best when cimetidine was the reference permeability drug and weakest when metoprolol was used [51].

10.4 DETERMINANTS OF ORAL BIOAVAILABILITY

Given that the majority of drugs are administered as an oral dosage form, the role of the GI tract is significant in the disposition of many drugs. The GI tract serves many important functions involved in the digestion of food, absorption of dietary nutrients, exchanges of liquids, and excretion of waste products as well as providing a protective barrier to the entry of xenobiotics and other foreign matter such as bacteria [52]. Consequently, absorption into the portal circulation requires the physicochemical properties of a drug that govern solubility and permeability to be balanced with respect to physiology of the GI tract such as transit time, luminal content, pH environment, and absorptive surface area. The serial arrangement of the small intestine and liver also provide sequential barriers for drug transit to the systemic circulation.

For orally administered drugs, the amount of dose transferred from the site of administration to the systemic circulation will be determined by the fraction of absorbed dose as well as the available fraction not subjected to intestinal or hepatic first-pass elimination. Although some degree of passive permeability becomes a requisite feature for drug transfer across the gut wall, a component of bioavailability is also determined by drug affinity for transporters and metabolizing enzymes localized in the epithelial lining of the gut. Moreover, hepatocytes in the liver express a full complement of transporters and enzymes that may further limit drug transit to the systemic circulation. Thus, absorption from the GI lumen, metabolism by enzymes, and active transport processes localized in enterocytes, along with hepatic uptake and metabolism, are considered to be the major sources of drug loss following oral administration.

Oral bioavailability is a measure of the fraction of dose absorbed as intact drug from the GI lumen (F_a), the fraction transferred to the portal bloodstream without intestinal extraction (F_g), and the fraction not extracted on hepatic first pass (F_h) [1]. Thus, drug bioavailability can be estimated as a product of dose fractions that escape loss at each site during the sequential transit of intact drug from the GI tract to the liver and the systemic circulation. Accordingly, the determinants of oral drug bioavailability are related by the following expression:

$$F = F_a \times F_g \times F_h \quad (10.8)$$

The utility of this simple mathematic relationship can be illustrated by considering the example of raloxifene, a selective estrogen receptor inhibitor that exhibits low

oral bioavailability. After oral administration, $\sim 2\%$ of a raloxifene dose enters the systemic circulation as parent drug with the balance lost to malabsorption and first-pass elimination. Prior knowledge of the fraction of dose absorbed as intact raloxifene (63%), plus the fraction of dose that evaded hepatic extraction (59.3%), allows an estimate of the fraction of dose transferred across the gut mucosa. Using the above expression to solve for F_g , in which $F_g = (63\% \times 59.3\%)/(2\%)$, $\sim 5.4\%$ of the fraction of absorbed dose escaped intestinal extraction, suggesting that first-pass gut extraction is the major limitation to raloxifene oral bioavailability [53].

The bioavailability of orally administered drugs is determined by drug absorption and intestinal and hepatic first-pass elimination, as described by Equation 10.8. To understand the mechanisms responsible for incomplete drug bioavailability, limitations to absorption as well as first-pass elimination by the gut and liver must be determined separately. Experiments conducted in cannulated animal models have offered an approach to study drug loss in a physiologically intact system. Frequently, drug extraction or loss is measured by infusing drug at multiple sites of input (i.e., intra-arterial, IV, duodenal, and intraportal) and sampling from a single venous site in a rodent model. Alternatively, extraction can be determined by infusing drug at a single catheter site and sampling at multiple sites [54]. A five-catheter chronic rat model has also been used to assess drug bioavailability in animals that have fully recovered from surgery and anesthesia associated with catheter placement. This model records drug extraction under normal physiologic conditions as GI and liver functions are returned to presurgery status before experiments are initiated [55]. Although surgical approaches have frequently been adopted to elucidate the determinants of oral bioavailability in preclinical animal models, the use of invasive techniques is not common in human subjects.

10.4.1 Oral Drug Absorption

10.4.1.1 Approximation of F_a . In clinical studies, an estimate of F_a is frequently provided by monitoring the cumulative excretion of a single dose of radiolabeled drug. For drugs in which both parent and metabolites are eliminated by renal excretion, the proportion of total radioactive dose excreted into urine $[(Au,rad)/dose]$ can be used to approximate the fraction of absorbed dose. Comparison of total radioactivity excreted after oral (po) and IV dose administrations provides an estimate of F_a according to the following expression:

$$F_a \cong \frac{(Au,rad)_{po}}{(Au,rad)_{iv}} \times \frac{(Dose)_{iv}}{(Dose)_{po}} \quad (10.9)$$

Although Equation 10.9 requires determination of the proportion of IV dose eliminated in urine, IV data are frequently not available. However, in some cases, F_a can be estimated from oral dose data only, such as with the cyclooxygenase-2 inhibitor rofecoxib [56]. In the case of rofecoxib, F_a could be approximated from radioactivity excreted after oral dosing (Eq. 10.10) because the fraction of total radioactivity in urine represented a relatively large proportion of overall rofecoxib elimination:

$$F_a \cong \frac{(Au,rad)_{po}}{(Dose)_{po}} \quad (10.10)$$

Modest improvements in estimates of the fraction of absorbed dose have also been achieved by application of Equation 10.10 plus consideration of metabolite levels excreted in feces as a percent of dose. In the case of the antipsychotic drug olanzapine, the fraction of absorbed dose was approximated by the sum of total radioactive dose recovered in urine plus the fraction represented by excretion of the 10-*N*-glucuronide metabolite in feces [57]. However, a caveat to this approach assumes that metabolite was excreted into feces and not formed by biotransformation of either unabsorbed dose or excreted parent drug returned to the GI tract.

10.4.1.2 Dissolution and Solubility. The fraction of an oral dose absorbed from the GI tract is a function of the physicochemical properties of a drug substance, as absorption can be limited by incomplete dissolution of solid drug as well as low intrinsic solubility. When administered as a tablet or capsule, partial dissolution of solid drug or a slow rate of dissolution relative to transit times within the absorptive regions of the GI tract may limit drug absorption. The intestinal environment may also influence drug solubility. Because the luminal content of the small intestine is mostly water, aqueous solubility plays an important role in drug absorption. However, drug solubility and oral absorption can also be influenced by changes in gastric pH as well as the heterogenous composition of the intestinal lumen.

Most drug substances are either weak acids or weak bases that can become ionized under physiological conditions of the GI tract that ranges from low pH of the stomach (pH 0.8–1.8) to near neutral pH in the distal GI (pH 6.5–7.2) in the fasted state [58]. The degree to which a weak acid or weak base exists in an ionized or unionized state depends on pH of the local environment and the pK_a of the drug. Therefore, regional differences in pH along the GI tract can have an effect on the absorption of weak acids and weak bases caused by pH-dependent changes in solubility. The antifungal ketoconazole is an example of a weak base characterized by pH-dependent solubility and absorption. Owing to a low pK_a , weak bases such as ketoconazole have improved solubility under acidic conditions. Ketoconazole has two pK_a values (2.9 and 6.5) and is relatively insoluble near neutral pH, but solubility is dramatically improved at low pH conditions. Experimental evidence of the pH dependence of ketoconazole absorption was demonstrated in healthy volunteers. Oral ketoconazole bioavailability was increased when dosed in an acidic solution and decreased when gastric pH was raised by coadministration with the proton pump inhibitor cimetidine [59].

In addition to pH-dependent effects on solubility, bile salts in the intestinal lumen may also influence drug solubility and absorption. The aggregation of bile salts present in the small intestine form micelles that may enhance the solubility and absorption of some poorly water soluble drugs. The importance of bile salts to the dissolution and solubility of the antifungal agent griseofulvin and the steroid danazol have been proposed to explain enhancements in postprandial bioavailability of these agents [60]. Oral absorption of the cyclooxygenase-2 inhibitor rofecoxib is also believed to be facilitated by bile salts in the GI tract. Following oral [^{14}C]rofecoxib administration, the fraction of absorbed rofecoxib dose was lower in cholecystectomy patients than in healthy volunteers, suggesting enhanced rofecoxib intestinal solubility in the presence of bile [56].

10.4.1.3 Food Effects. The presence of food within the GI tract may further complicate processes leading to oral bioavailability, as changes in drug absorption and

systemic exposure may result from physiological changes caused by food. Following a meal, digestive processes initiate transient increases in gastric pH accompanied by slower gastric emptying as well as longer overall GI transit times. Changes in intestinal fluid composition which result from stimulated secretions from the pancreas, liver, and gallbladder may also affect drug absorption. Additionally, constituents of a meal such as fats, carbohydrates, and minerals, may interact directly with drug substances to influence absorption as well as with membrane transport proteins or enzymes responsible for drug disposition.

Predictions of the effect of food on drug absorption and systemic exposure have been afforded from estimates of relative solubility and permeability characteristics of different drug substances. Thus, grouping compounds based on BCS [43] and BDDCS [47] criteria provide a framework to predict the effects of a meal on bioavailability. However, although changes in physiology resulting from food intake are known, the mechanisms by which food may change the bioavailability of a given drug are not always straightforward. Moreover, the magnitude of effect due to individual mechanisms makes predictions of food effects even more challenging. For instance, the nonsteroidal anti-inflammatory drug ibuprofen is a weak acid characterized by low solubility and high permeability. With a meal, greater oral absorption of ibuprofen due to increased solubility at higher pH and prolonged gastric emptying time would be expected to improve bioavailability relative to fasting. However, following ingestion of a meal, ibuprofen bioavailability was decreased by ~20%, potentially due to drug binding to viscous chyme generated from the meal and rendering it unavailable for absorption in the proximal intestine [61].

The effects of a meal on oral absorption may result in an increase in drug exposure (positive food effect), a decrease in exposure (negative food effect), or an insignificant change in exposure. Although systemic exposures of many commonly prescribed drugs used in clinical practice can be altered when taken with a meal, dosing recommendations to instruct use with or without food are relatively uncommon. A representative sample of drugs having product inserts that contain dosing recommendations related to food intake are shown in Table 10.3. For many drugs that exhibit negative food effects, food restrictions are recommended in order to maximize systemic exposure. An extreme example is the bisphosphonate alendronate that requires dosing with water before the first food or beverage after an overnight fast in order to achieve ~1% oral bioavailability. For drugs that exhibit positive food effects, many are recommended with a meal as a means to improve bioavailability and achieve therapeutic concentrations. In many instances, variability in systemic exposure is decreased by food as the fraction of absorbed dose can be increased in the fed state. However, in the case of the tyrosine kinase inhibitor lapatinib, a positive food effect was associated with equivalent or slightly increased PK variability and therefore lapatinib dosing is recommended without food. The product insert of another tyrosine kinase inhibitor nilotinib also recommends a food restriction, although a high fat meal was shown to increase AUC exposure by 50% in patients and 82% in healthy volunteers [62]. Unique among the drugs with food interactions listed in Table 10.3 is the black box QTc safety warning of nilotinib that includes a description of food effects on drug exposure [63].

Interactions between drugs and multivalent cations present in foods and antacids can also lead to changes in drug absorption. The oral bioavailability of some drugs may decrease as a result of chelation, the formation of a complex between polar groups

TABLE 10.3 Representative Drugs with Package Inserts that Include Dosage and Administration Instructions Related to Food Intake

Drug	% <i>F</i> (Fasting) ^a	Package Insert Comments and Dosing Recommendations ^b
<i>Drugs with Positive Food Effects</i>		
Efavirenz	NA	Increased exposure when tablet was dosed with high fat meal; $C_{\max}$ (+79%; 1.79-fold) and AUC (+28%; 1.28-fold). Dosing recommended on an empty stomach. Dose: 600 mg q24h
Isotretinoin	40% (fed)	Owing to high lipophilicity, absorption is increased when dosed with a high fat meal; $C_{\max}$ (+170%; 2.7-fold) and AUC (+186%; 2.86-fold) for 80 mg dose. Dosing recommended with food
Lapatinib	NA	AUC is increased approximately threefold (low fat) to fourfold (high fat) with food. $C_{\max}$ increased ~2.5- to 3-fold. Dosing recommended at least 1 h before or after a meal. Dose: 1200 mg q24h
Lovastatin	≤ 5%	Increased exposure when dosed with food. Dosing recommended with meals. Dose: 10–80 mg q24h or 5–40 mg q12h
Nelfinavir Mesylate	— 20–80%	— Increased exposure and decreased PK variability with food. AUC is increased 2.2- to 5.2-fold with food and $C_{\max}$ is increased 2.0- to 3.8-fold with food. Dosing recommended with meals. Dose: 750 mg q8h or 1250 mg q12h
Nilotinib	NA	Black box safety warning to avoid food intake for at least 2 h before dosing due to associated QTc risk. Observed AUC increases of 50–82% when administered with a high fat meal. Dose: 400 mg q12h
Ziprasidone Hydrochloride	— 59% (fed)	— Increased bioavailability up to twofold when dosed with food. Dosing recommended with food. Dose (initial): 20 mg q12h
<i>Drugs with Negative Food Effects</i>		
Alendronate Sodium	— <0.7%	— Owing to poor solubility, absorption is decreased with food or beverages other than plain water. Dosing recommended a least 30 min before first food or beverage of the day
Lansoprazole	81%	Decreased exposure when dosed 30 min after meals; $C_{\max}$ (–50%) and AUC (–70%). Dosing recommended before a meal. Dose: 15–30 mg q24h
Riluzole	64%	Decreased bioavailability when dosed with food; $C_{\max}$ (–45%) and AUC (–20%). Dosing recommended at least 1 h before or 2 h after a meal. Dose: 50 mg q12h
Tegaserod Maleate	— 11%	— Decreased bioavailability when dosed with food; $C_{\max}$ (–20% to 40%) and AUC (–40% to 65%). Dosing recommended before a meal. Dose: 6 mg q12h
Valsartan	23%	Decreased exposure when dosed with food; $C_{\max}$ (–50%) and AUC (–40%). Dosing recommended with or without food. Dose: 80/160/320 mg q24h
Voriconazole	96% ^b	Decreased $C_{\max}$ (–34%) and AUC (–24%) with high fat meal. Dosing recommended at least 1 h before or 1 h following a meal. Dose: 200 mg q12h

Abbreviation: NA, not available.

of a drug molecule and multivalent metal ions, such as aluminum, calcium, and magnesium. Chelates formed between drug substances and meal ions may impair tablet or capsule dissolution or may cause solubilized drug to precipitate in the gut lumen. The oral bioavailabilities of several antibiotic agents, such as the tetracyclines, oral cephalosporins, and quinolones, have been decreased by the formation of stable chelate complexes in the gut lumen. For example, decreased absorption of the quinolone antibiotic ciprofloxacin due to interaction with multivalent ions from dietary supplements, antacids, and phosphate-binding agents have been associated with 38–54% decreases in bioavailability [66,67].

10.4.1.4 Stability. Oral absorption may also be curtailed for drug substances prone to instability within the GI tract. The fraction of an oral dose that is absorbed from the GI tract can be limited by drug loss in the lumen due to decomposition or chemical degradation (e.g., pH-dependent processes) as well as by microbial or enzyme-mediated degradation.

Acid-labile drugs such as the immunosuppressive agent erythromycin and the reverse transcriptase inhibitor didanosine are unstable in the acidic environment of the upper GI tract. Didanosine undergoes acid-induced hydrolysis in the stomach and has been formulated with antacid in order to improve its oral absorption profile and bioavailability. More recently, introduction of didanosine as an enteric coated capsule has improved drug stability by avoiding contact with the acidic environment of the stomach and eliminated the digestive intolerance associated with the previous buffered oral formulation [68].

In addition to pH-dependent stability, the fraction of absorbed dose may also be modulated for drugs susceptible to metabolism by GI microflora. Bacteria residing in the large intestine contribute to normal digestive function by fermentation of carbohydrates and proteins that escape digestion in the upper GI tract. Drug substances may also be metabolized by enzymes in the gut microflora that typically catalyze chemical reduction and hydrolysis reactions [52,69]. In addition, metabolism of drugs by microbial enzymes may also be a function of the amount of intact drug reaching distal regions of the GI tract, consistent with an increased prevalence of microflora within the large intestine.

Drugs with low solubility and/or low permeability have a sufficiently long residence time in the gut to allow access to the distal GI tract. For instance, the peripherally acting μ -opioid antagonist alvimopan is hydrolyzed by amidases in intestinal flora to an equipotent metabolite that may contribute to PD effect. Evidence of a role for gut flora in alvimopan metabolite bioavailability was supported by coadministration of ciprofloxacin with alvimopan. Although alvimopan bioavailability, ~6%, was not changed by ciprofloxacin coadministration, metabolite concentrations were decreased by ~99% relative to the levels after alvimopan treatment alone. These findings were consistent with formation of a presystemic metabolite of alvimopan by amidases in intestinal flora [70]. Additionally, β -glucuronidases located in the distal region of the GI tract may catalyze the hydrolysis of excreted drug conjugates, leading to increases in systemic exposure by rendering parent drug available for reabsorption. Examples of drugs that undergo enterohepatic recirculation include indomethacin [71] and mycophenylatemofetil [72]. Mycophenylatemofetil is a prodrug that is completely absorbed after oral dosing and subsequently hydrolyzed to mycophenolic acid (MPA), the active immunosuppressive agent (Fig. 10.2). The elimination of MPA occurs mainly

Figure 10.2 Proposed scheme of mycophenolate mofetil metabolism and enterohepatic recirculation of mycophenolic acid. Approximately one-third of MPA oral exposure is attributed to enterohepatic recirculation. *Abbreviations:* MMF, mycophenolate mofetil; MPA, mycophenolic acid; MPAG, mycophenolic acid glucuronide.

by conjugation with glucuronic acid, which is partially excreted in bile. On excretion, the conjugated metabolite may be deglucuronidated by the gut microflora and reabsorption of the aglycone contributes to overall systemic exposure and immunosuppressive effects. A mean increase of ~37% in mycophenylatemofetil bioavailability was attributed to enterohepatic recirculation of MPA from a crossover study conducted with the bile acid sequestrant cholestyramine in healthy volunteers [72]. The extent of MPA reabsorption was similarly decreased by concurrent antibiotic therapy. In healthy volunteers, concomitant treatment with the antibiotic metronidazole was associated with a 36% decrease in oral AUC exposure of MPA [73]. Taken together, the interaction studies with cholestyramine or metronidazole suggested that ~35% of oral MPA exposure and bioavailability may result from enterohepatic recirculation of MPA.

10.4.1.5 Intestinal Transporters. The fraction of absorbed dose following oral administration is also a function of drug permeability across the intestinal wall. The permeability of a drug may be influenced by passive diffusion as well as active transport mechanisms. Passive permeability typically occurs by transcellular

or paracellular processes in which drugs diffuse across the intestinal wall from a region of relatively high concentration in the gut lumen to lower concentrations in the portal circulation. Depending on the characteristics of individual drug substances, recognition by membrane transporters lining the GI epithelium may also affect overall drug permeability.

Membrane transport proteins also have a role in intestinal drug disposition, as both efflux and uptake transporters may determine drug bioavailability. Efflux transporters are part of a superfamily of ATP-binding cassette (ABC) transporters that extrude drug in energy-dependent processes and may prevent drug absorption into the portal blood circulation when expressed in enterocytes in the gut. Uptake transporters responsible for drug disposition belong to the two solute carrier superfamilies, SLC and SLCO, involved in drug uptake via mechanisms of cotransport. SLC and SLCO proteins transport drugs according to a concentration gradient and may function to improve the degree of intestinal drug absorption. Together, the activities of many ABC transporters and solute carrier proteins expressed within intestinal epithelium have proven to affect drug oral bioavailability. A summary of clinical interaction studies implicating the role of individual transporters in oral drug bioavailability is shown in Table 10.4.

The efflux transporter P-glycoprotein (P-gp; MDR1), encoded by *ABCB1*, is expressed in multiple tissues important for drug disposition, including epithelia of the GI tract and hepatobiliary canaliculi as well as endothelia of the blood–brain barrier. In the gut, P-gp is localized at the apical membrane of enterocytes and may function as a barrier to absorption by transporting drug back to the lumen. Thus, recognition by P-gp has been considered a key determinant of oral bioavailability for an array of structurally diverse drugs. Substrates for P-gp transport generally tend to be hydrophobic and are represented by high molecular weight drugs such as paclitaxol and cyclosporine A (CsA) as well as smaller sized drugs such as talinolol [90]. Although *in vitro* and *in silico* models are frequently used to identify potential P-gp substrates, the impact of P-gp on oral drug bioavailability has been predicted with varying levels of success.

In addition to broad substrate recognition, the effects of P-gp on oral bioavailability are largely due to the expression profile of P-gp along the GI tract. P-gp is expressed in the luminal membrane (apical) of the small and large intestines where it plays a central role in the export of drug from epithelial cells such as enterocytes. Gradually increased from the proximal to distal regions of the human intestine, P-gp expression is heterogeneous along the GI tract, as mRNA levels measured in colon have been shown to be approximately sixfold higher than levels in the duodenum [91]. The significance of heterogeneous expression levels of intestinal P-gp and the effect on oral bioavailability was considered in an exploratory study with CsA. In human volunteers, drug absorption from different regions of the GI tract was studied by infusion of CsA into specific regions of the GI tract. Plasma concentrations of CsA revealed an absorbance profile of CsA with a rank order (stomach > jejunum/ileum > colon) that was consistent with changes in P-gp expression level (stomach < jejunum/ileum < colon) [92]. Differential expression of P-gp due to polymorphisms in *ABCB1* could be a further source of variation across individuals; however, the specific role of individual *ABCB1* polymorphisms in drug PK continues to be an area of active research [90].

A mechanistic role for P-gp in the absorption of some drugs has been assessed in mice deficient in *mdr1a/b* genes. Using the genetic mouse model, differences in oral

TABLE 10.4 The Role of Selected Human Transporter Proteins Implicated in the Bioavailability of Orally Administered Drugs

Drug	Modulator	Effect	References
<i>P-glycoprotein (ABCB1)</i>			
Digoxin	Talinolol	AUC _{po} (0–6 h) increased by 23%, due to P-gp inhibition	74
Docetaxel	OC144-093	Bioavailability increased from 8% without to 26% with OC144-093 cotreatment, due to P-gp inhibition	75
	Cyclosporin A	Absolute bioavailability was increased from 8% without to 90% with cyclosporine A cotreatment, due to P-gp and CYP3A4 inhibition	76
	Ritonavir	AUC _{po} /AUC _{iv} = 1.31–1.61 range: PO docetaxel (100 mg) + ritonavir (100 mg) compared with IV docetaxel (100 mg) alone	77
Paclitaxel	Cyclosporin A	Bioavailability was increased from 4% without to 28% with CsA cotreatment, due to P-gp and CYP3A inhibition	78
	GF120918	Bioavailability was increased to 30% with GF120918 cotreatment, due to P-gp inhibition	79
Talinolol	Carbamazepine	Bioavailability decreased from 62% without to 53% with CBZ cotreatment, due to P-gp induction	80
	SJW	Bioavailability decreased from 52% without to 39% with SJW, due to P-gp induction	81
	Digoxin	Digoxin had no effect on talinolol bioavailability; contrary to the observed decrease in digoxin exposure due to talinolol inhibition (see above)	74
<i>BCRP (ABCG2)</i>			
Topotecan	GF120918	Bioavailability increased from 40% without to 97% with GF120918 cotreatment, due to BCRP inhibition	82
Sulfasalazine	BCRP polymorphism	Sulfasalazine AUC _{po} was 2.4-fold greater in subjects with ABCG2 (34GG/421CA) variant than subjects with (34GG/421CC) genotype	83

<i>OATP1A2 (SLCO1A2)</i> Fexofenadine	GFJ	Bioavailability decreased by 42% with GFJ compared to water, due to OATP1A2 uptake inhibition	84
<i>OATP2A1 (SLCO2A1)</i> Aliskiren	GFJ	AUC _{po} exposure was decreased by 61% with GFJ, due to enteric OATP2B1 uptake inhibition	85
<i>OATP1B1 (SLCO1B1)</i> Atorvastatin	Rifampin	AUC _{po} exposure of atorvastatin acid was increased by 6.8-fold with rifampin IV infusion, due to hepatic OATP1B1 uptake inhibition. Single rifampin dose unlikely to induce CYP3A4	86
Atorvastatin	SLCO1B1 polymorphism	Mean atorvastatin AUC _{po} was 1.44-fold (144%) greater in subjects with the <i>SLCO1B1</i> c.521CC genotype than in those with the c.521TT genotype	87
Simvastatin	SLCO1B1 polymorphism	Mean simvastatin AUC _{po} was 2.21-fold (221%) greater in subjects with the <i>SLCO1B1</i> c.521CC genotype than in those with the c.521TT genotype	88
<i>OATP1B3 (SLCO1B3)</i> MPAG	SLCO1B3 polymorphism	MPA enterohepatic cycling was decreased in patients with the OATP1B3 (334G-669A) haplotype, due to reduction in MPAG hepatic uptake	89

absorption of the cytotoxic agent paclitaxel confirmed the importance of P-gp recognition and efflux [93]. The contribution of P-gp to oral paclitaxel PK was implicated by an observed increase in absolute bioavailability from 11% in wild-type mice to 35% in genetically modified mice. These predictions made from the mouse model were later corroborated in humans by demonstrating increased oral paclitaxel exposures on coadministration of transport inhibitors selective for P-gp. Consistent with the effect of P-gp efflux to limit oral absorption, the bioavailability of paclitaxel was approximately eightfold higher when dosed in combination with the P-gp inhibitor CsA than after oral paclitaxel alone [78]. Although CsA also inhibits metabolism by CYP3A4, the effect of CsA coadministration was attributed to an increase in paclitaxel absorption due to inhibition of P-gp efflux. This conclusion was supported by findings from a subsequent study in which a change in paclitaxel bioavailability of similar magnitude was observed on coadministration of the P-gp inhibitor GF120918 with paclitaxel [79]. Clinical interaction studies have also implicated P-gp efflux as a mechanism to limit the absorbed fraction of other oral agents such as digoxin, talinolol, and docetaxel, as shown in Table 10.4.

Breast cancer resistance protein (BCRP; encoded by *ABCG2*) is also expressed at the apical membrane of the small intestine. Similar to P-gp, BCRP may facilitate secretion of drugs such as the topoisomerase inhibitor topotecan back into the gut lumen, thereby reducing the absorbed fraction of an oral dose [82]. The modulating effects on drug absorption by uptake of SLCO transporters such as OATP1A2 and OATP2B1 expressed in the human small intestine have also been demonstrated. Inhibition of OATP1A2 uptake of fexofenadine by oral grapefruit juice was associated with a decrease in fexofenadine bioavailability [86]. Because fexofenadine is not metabolized by CYP3A, it was concluded that inhibition of OATP1A2 by grapefruit juice led to an observed decrease in fexofenadine oral bioavailability. Similarly, the effects of oral grapefruit juice leading to a 61% decrease in the oral AUC exposure of the antihypertensive agent aliskiren were attributed to inhibition of OATP2B1 uptake in the gut [85]. Although aliskiren is metabolized by CYP3A4, the net effect of concomitant grapefruit juice was to reduce exposure presumably due to inhibition of OATP2B1 uptake (Table 10.4).

10.4.2 Intestinal Extraction

10.4.2.1 Approximation of F_g . Drug extraction across the intestinal wall may also contribute to incomplete bioavailability after oral dose administration. The presystemic removal of drug on transfer from the GI tract to the systemic circulation is referred to as *first-pass drug elimination* [94]. Although the liver is generally assumed to be the major site of presystemic metabolism, the importance of first-pass intestinal extraction after oral dosing has been acknowledged for an increasing number of therapeutic agents. However, the contributions to first pass from intestinal extraction and hepatic extraction are not easily differentiated in clinical studies and therefore direct estimates of F_g are not always obtained experimentally. Instead, as described in the raloxifene example above, F_g is frequently determined algebraically from estimates of F_a , F_h , and F by Equation 10.8.

Experimental estimates of human first-pass intestinal metabolism have been obtained occasionally, generally following more invasive techniques. The relative contributions of intestine and liver to first-pass metabolism of cyclosporine and midazolam were

shown directly in anhepatic patients during liver transplant procedures [95,96]. In the study with midazolam, intestinal extraction (i.e., $1 - F_g$) was determined from arterial and hepatic portal venous concentrations of 1'-hydroxymidazolam and compared after IV and intraduodenal infusions of midazolam. The intestinal extraction of midazolam by the interduodenal route (0.43) was more than fivefold greater than that by the IV route (0.08), implicating a role for the small intestine in midazolam first-pass elimination. Nifedipine extraction by the intestinal mucosa has also been evaluated in patients with a portocaval anastomosis as well as in healthy volunteers using a multilumen perfusion catheter [97,98].

More recently, oral grapefruit juice has been used in clinical studies to implicate the role of the intestine in first-pass elimination of several drugs metabolized by CYP3A. Grapefruit juice contains furanocoumarin constituents known to irreversibly inhibit CYP3A in the gut mucosa [99,100]. A study in human volunteers with grapefruit juice demonstrated that the oral bioavailability of felodipine, a calcium channel blocker, was limited by intestinal first-pass elimination [101]. Relative to coadministration of water, chronic oral grapefruit juice consumption was associated with a 3.1-fold increase in felodipine AUC exposure. The observed increase in felodipine bioavailability was presumed to result from inhibition of intestinal CYP3A4, as a lack of effect on hepatic CYP3A4 activity by grapefruit juice was determined by the IV erythromycin breath test. Grapefruit juice interaction studies have indicated that intestinal metabolism may also contribute to the first-pass elimination of saquinavir [102] and atorvastatin [103]. A representative group of drugs that undergo presystemic elimination and the proportion attributed to intestinal first-pass metabolism is shown in Table 10.5.

10.4.2.2 Intestinal Metabolism. Drug-metabolizing enzymes expressed in human intestinal epithelial cells create a barrier to the oral bioavailability of several highly metabolized drugs. Consequently, drugs may be subjected to phase I biotransformation reactions as well as phase II conjugation reactions on absorption from the GI lumen. Among the enzyme activities present in the gut mucosa that are frequently involved in the metabolism of drugs are various members of the UDP glucuronosyltransferase (UGT), sulfotransferase (SULT), and CYP enzyme families.

Although multiple CYP enzymes expressed in the intestinal mucosa may contribute to presystemic drug metabolism, CYP3A is the most abundant in human intestine. On average, CYP3A (CYP3A4 and CYP3A5) accounts for ~80% of total immunoquantified CYPs in the proximal small intestine, with the expression of CYP3A5 being highly variable across individuals. The second most abundant CYP enzyme in the human intestine is CYP2C9, accounting for ~15% of intestinal CYPs [110]. In addition to the differential expression of various CYP enzymes, their heterogeneous distribution within the GI tract may also affect the bioavailability of some drugs. CYP3A is localized in epithelial cells, enterocytes, which largely compose the mucosal lining of the gut. Microsomal CYP3A content and catalytic activities vary along the length of the human intestine, generally highest in the duodenum, and decline progressively toward the distal region of the GI tract.

Conjugation reactions within the intestine may also contribute to first-pass metabolism and subsequent detoxification of many xenobiotics as well as endogenous compounds. The bioavailabilities of drugs such as raloxifene [111] and the antidiabetic agent troglitazone [112] are limited by glucuronidation that occurs as a result first-pass gut metabolism. Similar to liver, multiple human UGT enzymes are expressed in

TABLE 10.5 Clinical Interaction Studies of Representative Drugs That Undergo First-Pass Metabolism by Human CYP3A

Drug	Modulator	Effect	References
<i>First-Pass Metabolism</i>			
Atorvastatin $F_g = 0.24^a$	GFJ	Atorvastatin acid AUC _{po} increased by 2.5-fold with GFJ, due to gut CYP3A4 inhibition	103
Cyclosporin A $F_g = 0.41$	Ketoconazole	Bioavailability increased from 22% without to 56% with ketoconazole, due to gut and hepatic CYP3A4 inhibition	104
	Rifampin	Rifampin interaction showed CsA hepatic extraction (0.08) was much lower than intestinal extraction (0.60)	104
Felodipine $F_g = 0.45^a$	GFJ	AUC _{po} increased by 3.1-fold with GFJ, due to gut CYP3A4 inhibition	101
Midzalam $F_g = 0.57$	Erythromycin and GFJ	AUC _{po} was increased by 1.9 with GFJ (gut CYP3A4) and by 2.5-fold with erythromycin (gut and liver CYP3A4)	105
	IV/PO	Mean oral bioavailability was 30% (range 12–50%) with complete absorption and $F_h \sim 0.56$	106
Nilotinib $F_g > F_h$	GFJ	AUC _{po} exposure was increased by 29% with GFJ, due to gut CYP3A4 inhibition	107
	Ketoconazole	AUC increased by threefold with ketoconazole treatment, due to CYP3A4 inhibition	108
	Rifampin	AUC decreased by 80% with rifampin treatment, due to CYP3A4 induction	108
Tacrolimus $F_g = 0.14^a$	Ketoconazole	Bioavailability increased from 14% without to 30% with ketoconazole, due to gut and hepatic CYP3A4 inhibition	104
	Rifampin	AUC decreased twofold from 14% without to 7% with rifampin treatment, due to CYP3A4 induction	104
Saquinavir $F_g = 0.18^a$	GFJ	Bioavailability increased from 0.7% without to 1.4% with GFJ, due to gut CYP3A4 inhibition	102

Abbreviations: GFJ, grapefruit juice.

^aSource: Ref. 109.

the gut. Notably, the expression of two additional UGT enzymes, UGT1A8 and UGT1A10, is limited to the human small intestine [113,114].

Sulfate conjugation in the gut mucosa also constitutes a pathway of presystemic metabolism for endogenous compounds and drug substances. SULT expression levels in the small intestine are characterized largely by SULT1B1 and SULT1A3 [115,116]. For the adrenergic agonists albuterol, isoproterenol, and terbutaline, intestinal first-pass metabolism by sulfoconjugation is known to limit the bioavailability of each. Although these drugs are administered by inhalation to the lungs, a significant proportion of the dose is swallowed and subjected to gut first-pass metabolism. In the case of albuterol, enantioselective metabolism of the pharmacologically active (R) antipode indicated preferential bioavailability of the (S)-enantiomer from the intestinal tract [117]. In contrast to the higher expression levels of drug-metabolizing enzymes located in the liver, intestinal levels of SULT enzymes have been shown to exceed those of the liver [115].

10.4.2.3 Enzyme–Transporter Interplay. The efficiency of the human GI tract to limit the bioavailability of drug to the systemic circulation is due to a combination of factors that include GI physiology as well as the physicochemical attributes of drug substances. For many drugs, the extent of first-pass metabolism by CYP3A in the intestine is an important determinant of bioavailability. The relatively high expression level of intestinal CYP3A, ~80% of the total intestinal CYP content, localized at the epithelial layer of the gut mucosa make the proximal region of the small intestine well suited as a barrier to drug bioavailability. Additionally, the efflux transport protein P-gp functions to limit drug absorption from the gut lumen. Although CYP3A and P-gp are localized at the intestinal epithelium, the relative levels of each protein are differentially expressed in opposing direction along the GI tract. The expression pattern of CYP3A, highest in the proximal intestine and decreasing toward the distal regions, is complimentary to the progressive increase in P-gp levels toward the distal end of the GI tract.

In addition to the physiology of the human GI tract, bioavailability is also a function of the physicochemical properties of individual drug substances [118,119]. Although the active sites of CYP3A and P-gp may accommodate molecules that vary widely in size and chemical structure, substrates of these proteins share greater similarities with respect to the characteristics of hydrophobicity and permeability. Relative similarities in hydrophobic nature and membrane permeability that confer enzyme and transporter protein recognition are highlighted by the fact that most CYP3A substrates are also substrates or inhibitors of P-gp [120,121]. Moreover, the coordinate regulation of both CYP3A and P-gp by a single orphan nuclear receptor SXR has also been reported [122,123]. Taken together, the common physicochemical properties leading to overlapping substrate specificities and induction mechanism, plus coexpression in the epithelial layer of the gut mucosa with complimentary distributions along the GI tract, have led to a hypothesis that these proteins work together to coordinate an absorption barrier to drug transfer [104,124].

The relative importance of intestinal first-pass metabolism as a determinant of the bioavailability of some drugs has not been consistently predicted by CYP enzyme levels in human liver and intestine. Although estimates of total hepatic CYP content, ~25,000 nmol [125], far exceed estimates of enteric CYP levels, estimated at 78 nmol [126], intestinal metabolism has been found to account for a large proportion of the first-pass elimination of CYP3A substrates such as CsA [104,127] and midazolam

[96]. The importance of intestinal extraction has been explained in part by potential differences in unbound drug concentration within the gut lumen and portal bloodstream that could account for restricted access to hepatic enzymes due to plasma protein binding. Additionally, the functional interplay between intestinal CYP3A and P-gp has also been proposed to explain efficiencies of the gut mucosa to limit oral bioavailability of some drug substances [104,124,128]. CYP3A4, like all CYP enzymes, has a finite capacity to metabolize drugs. Following oral tablet dissolution and solubilization, high intraluminal concentrations of drug available for absorption could lead to CYP3A saturation and increased uptake of intact drug. However, the enteric localization of P-gp with CYP3A suggests that drug efflux to the lumen could provide a mechanism by which intracellular drug concentrations are maintained below levels that would otherwise saturate metabolism.

A simplified scheme depicting the coordinated interaction between CYP3A and P-gp in the human intestine is shown in Fig. 10.3. In this simplistic model, intact parent drug (P) absorbed into the enterocyte is presented with three available outcomes—(a) transcellular diffusion into the portal circulation as intact drug, (b) biotransformation to metabolite (M) with subsequent diffusion to portal blood, and (c) extrusion by P-gp out of the enterocyte and returned to the intestinal lumen. Effluxed drug (P') in the lumen may be reabsorbed by passive diffusion and the cycle begins anew. As luminal concentrations of drug are decreased along the GI tract, increasing proportions of absorbed drug are available for metabolism. In effect, the repeated cycle of absorption and efflux maintains low intracellular drug concentrations and thereby P-gp may control access of drug to intestinal CYP3A enzymes.

10.4.3 Hepatic Extraction and Uptake

10.4.3.1 Approximation of F_h . After incomplete dose absorption and first-pass metabolism within the gut mucosa, additional drug loss by hepatic extraction may further limit oral bioavailability. Once the absorbed fraction of parent drug enters the portal venous circulation, elimination by hepatic metabolism may occur on first passage through the liver. In clinical studies, the determination of drug clearance following

Figure 10.3 Proposed barrier to oral drug bioavailability involving P-glycoprotein and CYP3A localized at the intestinal epithelial cell layer. E, CYP3A4; M, metabolite; P, intact parent drug; P', effluxed parent drug; T, P-glycoprotein transporter. *Source:* Adapted from Ref. 124. (See color insert.)

IV administration can provide a measure of hepatic availability. An estimate of F_h is provided by determining hepatic extraction (E_h) as the proportion of hepatic plasma flow ($Q_{h,pl}$) represented by systemic drug clearance after IV dosing, according to the following expression [15]:

$$F_h = 1 - E_h = 1 - \frac{CL}{Q_{h,pl}} \quad (10.11)$$

in which $Q_{h,pl}$ is calculated from the product of liver blood flow and (1 - hematocrit), and the estimate of liver blood flow calculated from the product of body weight and 0.0216 L/min/kg [106]. Assuming that drug loss due to metabolism in the intestinal epithelium is negligible after IV dose administration, hepatic availability can be estimated by Equation 10.11. Although the estimation of F_h may be influenced by clearance within the intestine following IV dosing, it is generally assumed to be a minor contributing factor. For instance, when measured in patients during the anhepatic phase of liver transplantation, midazolam extraction across the gut mucosa was ~8% following IV dosing [96]. However, an assumption of negligible enteric metabolism after IV dosing could lead to incorrect estimates of F_h and consequently the role of gut extraction in limiting oral bioavailability might be underestimated [129].

Many of the drug-metabolizing enzymes localized in the gut mucosa which contribute to first-pass drug elimination are also expressed in the liver at much higher levels. Metabolism by CYP3A4, the most abundant human P450 enzyme, contributes to intestinal as well as hepatic first-pass elimination of several drugs. Although CYP3A4 metabolism may occur in each tissue, the proportion of oral bioavailability limited by either intestinal metabolism or hepatic metabolism varies for different drugs. For instance, intestinal first-pass metabolism by CYP3A4 is more significant for drugs such as the immunosuppressive agents tacrolimus and cyclosporine and the protease inhibitor saquinavir ($F_g < F_h$). Conversely, hepatic first-pass metabolism predominates for the lipid-lowering agent simvastatin and calcium channel blocker nifedipine ($F_g > F_h$) [109].

Contributions to hepatic first-pass extraction by the polymorphic CYP2D6 have also been shown by comparing drug disposition in extensive and poor metabolizer individuals. For instance, the antitussive agent dextromethorphan is rapidly absorbed and undergoes first-pass metabolism catalyzed largely by CYP2D6 with a lesser contribution by CYP3A4. The bioavailability of oral dextromethorphan has been shown to range from ~1% to 2% in extensive metabolizers to ~80% in poor metabolizers, indicating the importance of CYP2D6 in dextromethorphan first-pass metabolism [130]. Similarly, for the antimuscarinic agent tolterodine and the *N*-methyl-D-aspartate (NMDA) receptor antagonist traxoprodil, determinants of oral bioavailability included the CYP2D6 phenotype of individual subjects. Tolterodine exhibits first-pass metabolism, and oral exposures in CYP2D6 poor metabolizer individuals were ~30-fold higher than in extensive metabolizers [131]. Traxoprodil also undergoes hepatic first-pass metabolism by CYP2D6 and absolute oral bioavailability was ~80% in poor metabolizer subjects. Oral bioavailability appeared to be linear and independent of dose in poor metabolizer subjects, in contrast to extensive metabolizers in which oral bioavailability appeared nonlinear and dose dependent [132].

Limitations in oral drug bioavailability due to hepatic first-pass extraction may also occur for substrates of membrane transport proteins. The effects of hepatic uptake

transporters on oral bioavailability can be exemplified by the role of OATP1B1 in statin disposition. Although all statins are substrates for OATP1B1, polymorphisms in *SLCO1B1* expression have been associated with differential effects on the bioavailabilities of individual statins. For some statins, such as simvastatin, pitavastatin, and atorvastatin, variability in systemic exposure has been related to *SLCO1B1* genotype [87,88]. However, for other statins, such as fluvastatin, oral bioavailability appears to be independent of OATP1B1 genetics [133].

10.5 SUMMARY

The therapeutic use of a given drug is determined by factors associated with its pharmacological effect as well as safety. Inherent to both efficacy and safety is drug bioavailability, the proportion of dose to reach the systemic circulation, or site of pharmacological activity. For orally administered drugs, bioavailability may be limited by malabsorption from the GI tract as well as presystemic elimination by the gut mucosa and liver. Although the barriers to oral bioavailability have historically been considered as individual limitations, experimental research increasingly suggests that drug-metabolizing enzymes and transporters may provide a coordinated barrier to the portal circulation [124,134].

Estimation of bioavailability may be confounded by differences in drug PK, as low oral bioavailability has been associated with greater variability across patient populations [17]. Greater variability in PK can also affect bioequivalence testing as larger study groups are often required to provide sufficient statistical power to differentiate drug formulations. Although bioavailability studies frequently employ a crossover design within the same group of subjects in order to minimize PK variability between individuals, the use of isotopically labeled drug as well as microdosing approaches may also improve bioavailability estimation [22]. Moreover, accounting for sources of variability in enzyme as well as transporter expression and function may also improve the estimation of drug bioavailability.

While bioavailability studies relate systemic exposure to drug absorption and help understand mechanisms underlying drug distribution, transport, and metabolism, comparative bioavailability studies are conducted to evaluate the performance of one or more drugs or drug products against a previously defined reference. The bioequivalence of test and reference formulations for both new drug as well as generic drug products permits an assumption of therapeutic equivalence as well as the potential for product substitution.

11.1 SUMMARY

Early projection of human pharmacokinetic (PK) properties is of great significance for decision making at several stages in drug discovery and development (e.g., lead compound selection and optimization, first dose in human), and the interspecies allometric scaling is an important tool widely used in the industry for this type of prediction. The allometric scaling is an empirical method that has interested biological and pharmaceutical scientists for more than 100 years. It is developed based on cross-species similarities in anatomy, physiology, and biochemistry with a power function correlating physiological parameters with body size ($Y = aW^b$, where Y is the parameter of interest, W is the body weight, and a and b are the coefficient and exponent of the allometric equation, respectively). The allometric scaling method has been used successfully to describe a number of physiological and anatomical properties and has been applied to the projection of human PK for small-molecule drugs as well as therapeutic proteins. However, for most small-molecule drugs with high cross-species variability in hepatic metabolism, this method may not work well in the extrapolation of hepatic metabolic clearance (CL) from laboratory animals to humans. To improve the predictability of metabolic CL in humans, several modified scaling methods have been recommended and tested. Boxenbaum in 1983 proposed using maximum life span potential (MLP) and brain weight (BRW) as correction factors in allometric scaling since longevity

is frequently inversely correlated with hepatic cytochrome P450 drug oxidation rates. His work was later supported by the research of other scientists, and their work also demonstrated that the MLP and BRW correction improved the accuracy of human CL prediction when the allometry power exponent b was higher than 0.80—0.90. In 1997, Lave *et al.* integrated the *in vitro* data into the power function by normalizing the *in vivo* CL with *in vitro* metabolic CL and successfully applied their method to human CL prediction of 10 small-molecule drugs that are mainly hepatically eliminated. Nagilla and Ward in 2004 suggested using liver blood flow (LBF) as a correction factor for the scaling of small-molecule drugs. On the basis of their analysis of 103 compounds comparing simple allometry (SA) with LBF or MLP/BRW correction, they concluded that scaling with monkey LBF was the best approach among the methods tested (68% success rate). These modified scaling methods have improved the accuracy of prediction to some extent and are reviewed in this chapter. In recent years, there is an increasing interest in physiologically based pharmacokinetic (PBPK) and cell-based pharmacokinetic (CBPK) modeling. Both approaches are developed based on similar assumption that PK properties could be scaled-up from animals to humans according to fundamental physiological principles. These advanced methods allow the integration of input information from different sources (e.g., physiological and physicochemical properties of a drug molecule, permeability and binding affinity from *in vitro* experiments, PK profiles from animal tests and clinical trials). In addition to the prediction of PK parameters (e.g., CL, volume of distribution), the PBPK and CBPK models could also predict the concentration–time profiles in human blood as well as in tissues associated with efficacy and/or toxicity. The utility of PBPK and CBPK modeling goes beyond the prediction of “first-in-human trial,” as it has the potential to be continuously updated with new information (physiological and drug related). Some of the tools and techniques employed in PBPK and CBPK modeling are discussed in the second half of this chapter.

11.2 ALLOMETRIC SCALING

The allometry method was originally developed based on the assumption that mammals generally have similar anatomy, physiology, biochemistry, and cellular structure. This similarity would allow the extrapolation and scaling of physiologic properties (e.g., heart rate, blood flow, blood volume, organ size, longevity) from animals to humans (Fig. 11.1). A power equation $Y = aW^b$ is often used in allometric scaling, where Y is the physiologic variable of interest, W is body weight, and $\log a$ and b are the y -intercept and slope obtained from the plot of $\log Y$ versus $\log W$, respectively. Animals commonly used in preclinical tests (i.e., mouse, rat, rabbit, monkey, and dog) may not eliminate drugs with the same rate and pathway as humans, and small mammals usually eliminate chemicals faster than large mammals. Since the elimination of many drugs is associated with physiologic properties well described among species (e.g., size and blood flow for the elimination organs), it is assumed that drug elimination may be scaled among mammals, and many successful case studies have been reported in the literature [1–32]. However, the majority of the small-molecule drugs are eliminated via oxidative hepatic metabolism. If there are significant cross-species differences in substrate specificity and/or in enzymes activity, the animal to human extrapolation may

Figure 11.1 Correlation of liver weight, LBF, and renal blood flow versus total body weight in laboratory animals and humans.

fail. To reduce the error in the prediction of metabolic CL in humans, several correction factors have been introduced and are discussed in this section. In recent years, biotechnologically derived peptides and therapeutic proteins have been developed as mainstream therapeutic agents. Peptide and protein drugs (i.e., macromolecule drugs) now constitute a substantial portion of the compounds under preclinical and clinical development in the pharmaceutical industry. The distribution and metabolism of protein-based biotech drugs often follow the mechanisms of endogenous and nutritional proteins with nonspecific proteolysis as a major elimination pathway [33–35]. Owing to their structural similarity as polypeptides, it is generally much easier to predict how peptide and therapeutic proteins will be distributed, metabolized, and eliminated, and they typically have much faster development cycles. As the handling of peptides and proteins is relatively well preserved between different mammalian species, allometric scaling is usually much more successful for macromolecules than for the traditional small-molecule drugs. In this section, the scaling of these two types of drugs is discussed and compared. For some therapeutic proteins, the elimination process is associated with both nonspecific proteolysis and specific receptor-mediated endocytosis and degradation. Owing to the limited number of receptors expressed on the membrane or in the cell, the receptor-mediated degradation process could be saturated at high drug concentrations. For those proteins mainly eliminated with receptor-mediated degradation, saturation of this process would result in an over-proportional increase in systemic exposure, and a decrease of systemic CL with increasing dose (i.e., nonlinear PK). For example, dose-dependent elimination and prolonged half-life at higher doses have been reported for protein drugs erythropoietin, cetuximab, thrombopoietin, and trastuzumab (Herceptin) [36–40]. When this occurs, the systemic CL becomes dose dependent and is generally estimated using the Michaelis–Menten equation. Similar problem may also occur in the scaling of small molecules.

11.2.1 Prediction of Human Clearance Using Single Animal Species with a Fixed Exponent

As mentioned above, a power equation $Y = aW^b$, with Y as the physiologic variable of interest and W as body weight, is generally used in the allometric scaling. When a

log transformation of the power function is performed, the power equation becomes

$$\log(Y) = \log(a) + b \times \log(W)$$

The coefficients a and b can be obtained from a plot of the body weight from several species against the PK parameter of interest on a log–log scale; $\log(a)$ is the y-intercept and b is the slope obtained from the plot of $\log(Y)$ versus $\log(W)$. In general, biological frequencies (e.g., heart rate per minute) have an exponent of -0.25 , biological time periods (e.g., circulation time, MLP) have an exponent of 0.25 , biological rates (e.g., CL, physiological flow rates, and metabolism) have an exponent of 0.75 , volume of distribution has an exponent of 1.0 , and body surface area has an exponent of 0.67 [2–4,32]. The allometric exponents for most drugs are in a similar range to those from the corresponding biological processes, with exponents of 0.60 – 0.80 for CL and 0.8 – 1.0 for volume of distribution (V_d). If the PK data are only available in a single animal species, the CL and V_d in the humans are often estimated using a fixed exponent of 0.75 and 1.0 , respectively. The authors have tested the single species (mouse, rat, dog, or monkey) scaling of CL using a fixed b value ranged from 0.60 to 0.85 , and the prediction errors from this analysis of 62 small-molecule and 32 macromolecule drugs are presented in Fig. 11.2 and Table 11.1. The results would suggest an optimal value of 0.70 – 0.80 for the exponent b and to use large animals (e.g., monkey or dog) for single species scaling [41]. In general, the error of human CL prediction is within twofold using monkey PK data and body weight. With the allometry exponent b fixed at 0.70 , 0.75 , or 0.80 , the average error was 1.88-, 1.87-, and 1.86-fold for small-molecule and 1.97-, 1.75-, and 1.61-fold, respectively, for macromolecule drugs. The average error of human CL prediction is higher for the small-molecule drugs using dog as a single species and ranged from 2.4- to 2.9-fold. For macromolecule drugs, the predicted human CL is generally within twofold of the observed value using dog data, with average error ranging from 1.6- to 1.8-fold.

As mentioned previously, LBF is another physiological variable highly correlated to body size and was tested by several groups for its potential application in the extrapolation of hepatic metabolic CL from animals to humans [7,9,10]. The authors have evaluated recently [12] the use of LBF in single species scaling, and the results are summarized in Table 11.2. In general, the method works better for high CL drugs, and the average error of human CL prediction is 1.86- and 1.54-fold using monkey LBF and 2.9- and 2.3-fold using dog LBF for small- and macromolecule drugs, respectively. The average error of human CL prediction is much higher using mouse or rat data (body weight or LBF) for single species scaling [42].

11.2.2 Prediction of Human Clearance Using Two or More Animal Species

In general, allometric scaling is performed using two, three, or more animal species, and many successful case studies have been reported in the literature [1–32]. Conventional allometric scaling often works fairly well in human CL projection when the elimination process is dependent on kidney blood flow or LBF. However, for small-molecule drugs with significant cross-species differences in hepatic metabolism, simple allometric relationships may give poor prediction. Boxenbaum has suggested incorporating MLP into the allometric equation as a correction factor for the scaling of CL ($\text{MLP} \cdot \text{CL} = aW^b$) since longevity is frequently inversely correlated with hepatic

(a)

(b)

Figure 11.2 Cross-species comparison of the relationship between prediction error [average fold error (AFE)] and allometry exponent b for small-molecule (a) and macromolecule (b) drugs.

cytochrome P450 drug oxidation rates [2,3]. $MLP \cdot CL$ is the total volume from which drug would be cleared per MLP assuming constant drug exposure [2]. With regard to humans, it would appear that the relatively low CL (with respect to liver weight) is paced to their longevity, that is, activity is conserved so as to be extended over a relatively longer chronological MLP . Boxenbaum also explored the possibility of using BRW as a correction factor ($BRW \cdot CL = aW^b$) since MLP is closely correlated to BRW [$MLP = 10.839 \cdot (BRW)^{0.636} \cdot (W)^{0.225}$].

Consistent with Boxenbaum's proposal, Feng and others [5–7] also reported that correction with MLP or BRW could help to reduce the error in human CL prediction

Average fold error		2.93	2.26	1.86	1.54

^aThis approach predicts human CL according to the following equation: Predicted $CL_{\text{human}} = CL_{\text{monkey}} (LBF_{\text{human}}/LBF_{\text{monkey}})$, where liver blood flow is 21 and 45 mL/min/kg in human and monkey, respectively, as reported in the literature. For a human weighing 70 kg and a monkey weighing 5 kg, the liver blood flow is 1470 and 225 mL/min, respectively.

for small-molecule drugs with SA exponent b higher than 0.85. Examples from Feng's research are presented in Table 11.3. For the seven small-molecule drugs overpredicted using SA ($CL = aW^b$), incorporating BRW into the power equation ($BRW \cdot CL = aW^b$) increased the accuracy of human CL prediction and reduced the average error from 9.13- to 1.82-fold. Additional research from Mahmood [8,13–17] and Tang *et al.* [18] also supported the use of MLP and BRW as correction factors. Mahmood *et al.* and Balian [17] analyzed several series of small-molecule drugs and proposed three approaches for human CL prediction based on the value of the exponent b derived from the power equation $CL = aW^b$. They suggested incorporating MLP into the allometric relationship ($MLP \cdot CL = aW^b$) when the power exponent b is between 0.71 and 1.0 (0.75–0.90 from analysis of nine anticancer drugs) and correcting with BRW ($BRW \cdot CL = aW^b$) when b is higher than 0.90 or 1.0.

On the basis of a similar mechanism, a combined method of SA and multiexponential allometry (MA) was proposed to improve the accuracy of human CL prediction [19]. For the MA approach, human CL was estimated by the equation $CL = aBW^b + cBW^d$, where a and b are the coefficient and slope generated from the SA scaling and c and d are the coefficient and slope for MA. The parameter d is derived based on the slope from the scaling of blood flow rate, organ volume, and organ weight of liver or kidney versus body weight in preclinical species. The slopes of weight, volume, and flow rates of these major excretory organs (liver or kidney) are very similar and approximately

TABLE 11.3 Human CL Prediction with (CL·BRW = aW^b) or without (CL = aW^b) Brain Weight (BRW) Correction

Drug	Exponent b From SA	Actual Human CL (mol/min/kg)	Predicted/Actual	
			SA	CL × BRW
PD-7	0.97	0.0043	5.6	0.74
PD-8	1.1	8.5	5.7	1.5
Antipyrine	0.93	0.46	11.5	1.8

Midazolam	2.15	11	12.3	2.0
Average fold error			9.13	1.82

equal to 0.9. Therefore, the slope d was fixed as 0.9. The coefficient c was defined as a function of a and b :

$$c = a \left[\frac{(1 - \frac{3}{2}b)}{(1 - \frac{1}{2}b)} \right]$$

As reported by Goteti *et al.* [19], the proposed method helped to reduce the error of human CL prediction for small-molecule drugs with allometry exponent b higher than 0.7. The authors have evaluated the SA + MA method for the human CL prediction of 62 small-molecule drugs and compared with the SA approach with the results presented in Table 11.4. It appears that the SA + MA combination, although still empirical, reduced the average prediction error from 4.2- to 3.1-fold. However, the prediction errors still appear high for these small molecules using the SA + MA approach.

Although the prediction of human CL appears complicated and sometimes problematic for the small-molecule drugs, the SA method generally could predict human CL within twofold for the macromolecule drugs (i.e., therapeutic proteins). The authors have analyzed 32 macromolecule drugs and the outcome is presented in Table 11.4. The average error of human CL prediction is 2.1-fold using the SA, suggesting that the predicted values are normally within twofold of the observed human CL for these protein drugs, probably because the major elimination pathway for these therapeutic proteins is nonspecific proteolysis that is not species-dependent and very different compared to the complicated oxidative metabolic pathway for the small-molecule drugs. The results also recommend no correction factors for the scaling of these protein drugs since the SA method produced the lowest average error for human CL prediction (Table 11.4).

11.2.3 Integration of *In Vitro* Metabolic Clearance into Allometric Scaling

With the recent increase in the availability of human liver tissue, metabolic CL in humans may be estimated by a physiological approach using liver microsome, hepatocytes, expressed liver enzymes, or liver perfusion techniques [1,20–28]. Using the below equation, the hepatic blood CL ($CL_{b,H}$) in humans is calculated based on the intrinsic CL (CL_{int}) determined from an *in vitro* system, the LBF (Q_H), and the free fraction in human blood (f_{u_b}).

TABLE 11.4 Multiexponential Allometric Scaling

Drug Molecule <i>N</i>	SA		MA		SA + MA		SA + MLP

Fold error > 2	19	4	40	7	30	8	13	9

^aSA = simple allometry, $Y = aW^b$. MA = multiexponential allometry, $CL = aW^b + \left[\frac{1-1.5b}{1-0.5b}\right]aW^b$. SA + MA = rule of exponent—exponent >0.7, MA; exponent <0.7, SA. SA + MLP = rule of exponent—exponent >0.7, corrected by MLP; exponent <0.7, SA.

$$CL_{b,H} = \frac{Q_H \cdot fu_b \cdot CL_{int}}{Q_H + fu_b \cdot CL_{int}}$$

The *in vitro* systems (i.e., liver microsome, hepatocytes) possess many major drug-metabolizing enzymes and are thus useful tools for the *in vitro* to *in vivo* extrapolation and the prediction of the hepatic metabolic CL in humans. The details of this methodology are discussed in the chapters titled **Review of Drug Metabolism in Drug Discovery and Development**, **In Vitro and In Vivo Models of Drug Metabolism**, and **Enzyme Kinetics of Drug-Metabolizing Reactions and Drug–Drug Interactions** of this encyclopedia.

As mentioned previously, if there are significant cross-species differences in drug metabolism, the allometric scaling method may not work well. A modified power equation was proposed by Lave *et al.* in 1997 by integration of the *in vitro* data into the allometric relationship to improve the accuracy of hepatic CL prediction in humans. As listed in the following equation, the *in vivo* CL was normalized by the ratio of CL_{int} between the corresponding animal species and man, where CL_{int} is obtained from the *in vitro* experiment using liver microsome or hepatocytes and W is the body weight [29]:

$$CL_{man} = CL_{animal} \left(\frac{CL_{int,man}}{CL_{int,animal}} \right) \left(\frac{W_{man}}{W_{animal}} \right)^b$$

Comparing to the purely empirical approaches, Lave's method using both *in vitro* and *in vivo* experiment data added a physiological exponent to the conventional allometric scaling and gave an opportunity to integrate some of the complexities as discussed above. Lave successfully applied his method for the prediction of human hepatic metabolic CL for 10 compounds mainly eliminated hepatically [29]. Four small-molecule drugs (antipyrine, mibefradil, propranolol, and theophylline) from Lave's list with an allometry exponent $b > 0.80$ and an overpredicted human CL from SA are summarized in Table 11.5. The results suggest that correction with BRW or CL_{int} could improve the accuracy of human CL prediction and Lave's approach appears slightly better than the BRW method. The average error of human CL prediction is 4.84-, 1.86-, and 1.61-fold for SA, BRW, or CL_{int} correction, respectively. The scaling plots for propranolol with a comparison of all three methods are presented in Fig. 11.3. Propranolol human CL was nearly 3.5-fold overpredicted using SA (Table 11.5), with a scaling exponent of 0.82. The predicted propranolol human CL was 10.0 and 7.7 mL/min/kg using BRW and CL_{int} correction, respectively, and both are within twofold of the actual value reported in the literature (13.0 mL/min/kg).

11.2.4 Prediction of Volume of Distribution in Humans

Volume of distribution (V_d) or steady-state volume of distribution (V_{dss}) in humans is usually well predicted based on animal data. When we use the allometric power equation ($V_d = aW^b$, $V_{dss} = aW^b$) to perform human extrapolation, a plot is normally constructed of total (or unbound) volume of distribution in preclinical species (in units of liter or milliliter) versus animal body weight on a log–log scale for a test compound (Fig. 11.4). Linear regression is performed to determine the values of a and b , and these are then used, along with a standard value for human body weight (e.g., 70 kg), to predict the volume of distribution in humans. As mentioned previously, the allometric exponents for most drugs are in the range of 0.8–1.0 for the scaling of volume of

TABLE 11.5 Human CL Prediction for Antipyrine, Mibefradil, Propranolol, and Theophylline with Simple Allometry (SA), *In vitro* Metabolic Clearance (W_h), or Brain Weight (BRW) Correction

Drug	Exponent b from SA Scaling	Human CL (mL/min/kg)				Predicted/Actual		
		Actual	SA	CL $\times$ BRW	CL $\times$ W_h	SA	CL $\times$ BRW	CL $\times$ W_h
Antipyrine	0.93	0.46	5.3	1.2	0.25	11.5	2.6	0.54

distribution, similar to those from the corresponding biological processes. Boxenbaum in 1982 presented a close relationship ($V_d = 0.756 \cdot W^{0.961}$) between antipyrine volume of distribution and body weight in 11 species including human. His results indicated that the volume of distribution in humans could be successfully predicted using SA [3]. Research from Feng *et al.* [5–7] and other groups [14,31] also support the scaling of V_d or V_{dss} using allometry exponents of 0.8–1.0 with examples presented in Table 11.6 and Fig. 11.4. For the majority of the compounds, the steady-state volume of distribution (V_{dss}) in humans could be estimated using SA with the predicted values within twofold of the actual one (Table 11.6). Although the prediction of diazepam did not work well with the allometric analysis, the error was reduced to twofold when another method using the “average fraction unbound in tissues” was applied, and the details of this method are discussed below.

Obach *et al.* [31] have reported several methods for the prediction of volume of distribution in 1997. In addition to the SA, they also evaluated the contribution of protein binding, and the potential of using the dog–human proportionality or the average fraction unbound in tissues for human extrapolation. The dog–human proportionality method is developed based on the assumption that tissue binding of drugs is similar in dogs and humans, and the physiological parameters, such as extracellular fluid volumes, are similar between the two species on a per-weight basis. Therefore, proportionality could be set up between the free fraction of drug in plasma and the volume

TABLE 11.6 Prediction of Steady-State Volume of Distribution in Humans for 14 Drugs

Drug	Exponent	V_{dss} (L/kg)		
		Predicted (<i>P</i>)	Actual (<i>A</i>)	Ratio (<i>P</i>)/(<i>A</i>)
Cefotetan	0.98	0.21	0.13	1.56
Cefmetazole	0.85	0.15	0.14	1.03
Cefoperazone	0.93	0.17	0.14	1.21
Moxalactam	0.94	0.17	0.14	1.24
Cefpiramide	0.82	0.12	0.11	1.04
Cefazolin	0.98	0.17	0.11	1.60
Erythromycin	0.75	1.33	0.94	1.42
Oleandomycin	0.79	1.30	0.81	1.59
CI-921	0.67	0.29	0.32	0.91
Amsacrine	0.80	1.38	1.56	0.88
SK&F	0.93	0.20	0.24	0.80
Sumatriptan	0.97	2.53	1.64	1.55
Tolcapone	0.94	0.17	0.11	1.47
Diazepam ^a	1.36	7.05	0.89	7.93
Average	0.91	—	—	1.73

^aCorrected by protein bonding.**Figure 11.4** Allometric scaling of steady-state volume of distribution (V_{dss}) for cefotetan.

of distribution at steady state in these two species. The equation for the dog–human proportionality method is listed below, where the term “fu” designates the fraction of drug unbound in the plasma (or serum) in dog or human, and V_{dss} (human) and V_{dss} (dog) represent the volume of distribution at steady state in human (predicted) and in dog (actual), respectively, in units of L/kg.

$$V_{dss(\text{human, predicted})} = \left(\frac{fu_{(\text{human})} \cdot V_{dss(\text{dog})}}{fu_{\text{dog}}} \right)$$

For the method named as *average fraction unbound in tissues*, experimentally determined values for volume of distribution (in units of L/kg) and unbound fraction in plasma (f_u) for each species were used, along with standard values for extracellular fluid volumes, plasma volumes etc., to calculate the fraction unbound in tissues (f_{ut}) in animal species [43]. After f_{ut} was calculated for each of the preclinical species, all values for a given compound were averaged. This averaged animal value for f_{ut} is assumed to be equal to the f_{ut} in humans and, along with the experimentally determined f_u value for humans, was used in the prediction of human V_{dss} .

As listed in Table 11.7, the average error of human V_{dss} prediction was 1.6-, 1.6-, 1.8-, and 2.8-fold for the methods of “dog–human proportionality,” “average fraction unbound in tissues,” “SA with correction for f_u ,” and “SA without correction for f_u ,” respectively. On the basis of the results, Obach *et al.* recommended using the “dog–human proportionality” or the “average fraction unbound in tissues” method for the prediction of human V_{dss} in drug discovery and development.

As summarized in Fig. 11.5, early projection of CL and volume of distribution in humans is of great significance during drug discovery to assist in the optimization of drug PK characteristics. CL, when combined with the volume of distribution, gives the estimation of elimination half-life ($t_{1/2}$) of a drug. Hepatic metabolic CL, when combined with the fraction absorbed, determines the oral bioavailability ($\%F$) of a drug. Half-life and the oral bioavailability are key determinants of the dosing regimen of oral drugs, that is, size of dose and frequency of administration. Thus, the accurate prediction of CL and volume of distribution in humans is critical in the selection of

TABLE 11.7 Comparison of Various Methods Used for the Prediction of Steady-State Volume of Distribution in Humans

Method	<i>N</i>	Average Fold Error
Average fraction unbound in tissues	16	1.56
Dog–human proportionality	16	1.56
SA without correction of free fraction in plasma	14	2.78
SA with correction of free fraction in plasma	12	1.83

new lead compounds for progression into development, as new drugs on the market must not only be efficacious and safe but also be convenient to use for patients and physicians.

11.2.5 Prediction of Pharmacokinetic Profiles in Humans with Nonlinear Mixed Effects Modeling

The use of a nonlinear mixed effects model (NONMEM) as a single-step approach for interspecies scaling has offered certain advantages. This approach could estimate all the allometric parameters in one step and assess interindividual variability in the population. The PK parameters (e.g., CL or volume of distribution) for each species (including human) will then be calculated based on the body weight. The NONMEM equations often used for a two-compartment PK modeling following a single intravenous dose are listed below:

$$\begin{aligned} \text{TV}V_1 &= \theta_1(W)^{\theta_5} \\ \text{TV}V_2 &= \theta_2(W)^{\theta_6} \\ \text{TV}CL &= \theta_3(W)^{\theta_7} \\ \text{TV}Q &= \theta_4(W)^{\theta_8} \\ V_1 &= \text{TV}V_1 \cdot \exp(\eta_1) \\ V_2 &= \text{TV}V_2 \cdot \exp(\eta_2) \\ CL &= \text{TV}CL \cdot \exp(\eta_3) \\ Q &= \text{TV}Q \cdot \exp(\eta_4) \end{aligned}$$

where TV is the population estimate (or typical value) of the PK parameter; θ represents each of the allometric parameters; W is the body weight; CL represents the systemic CL; V_1 and V_2 are the volume of distribution for the central and the peripheral compartments, respectively; Q is the intercompartment CL; and η is the estimate of interindividual variability for each of the PK parameters.

A population pharmacokinetic model was developed and applied to the interspecies PK scaling of pegylated r-HuEPO (PEG-EPO). With NONMEM, the PK profiles of pegylated r-HuEPO (PEG-EPO) and the associated variability were appropriately described in all species (rat, rabbit, monkey, dog, and human) [44]. Another example is the interspecies PK scaling of sumatriptan using mixed effect modeling. The predicted kinetic parameters in each species were close to the actual values from the literature. The mixed effect modeling approach allowed the assessment of covariates associated with the physiologic status of animal (e.g., pregnancy) in the model, which resulted in an improved accuracy in the estimation of human PK parameters and concentration–time profiles [45].

The authors have assessed the interspecies allometric scaling of SK&F and propranolol using the NONMEM approach and the results are presented in Fig. 11.6 [45–50]. Animal data from rat, monkey, and dog were pooled and analyzed in one step using a mixed effect modeling approach (population), and the predicted PK parameters (CL, volume of distribution, etc.) and the plasma concentration–time profiles in humans are closely correlated with the observed values.

Figure 11.6 Prediction of human PK profiles using nonlinear mixed effects modeling (NONMEM). Symbols used for the preclinical PK plots: square, rat; triangle, dog; and circle, horse. Symbol and line used for the predicted human PK plots: square, observed human PK data and dashed line, upper and lower boundaries of the predicted human PK profile.

Recently, Tabata *et al.* reported a population pharmacokinetic (e-PPK) model for predicting human PK using exploratory ADME (absorption, distribution, metabolism, and excretion) data during early drug discovery research. The model was developed based on data of 11 internal compounds and validated with 12 external compounds. Among the data sets (internal and external references), the predictive performance has shown good consistency [51]. With the NONMEM approach, it is possible to model successfully more complicated allometric equations, to evaluate the potential contribution of physiological variables in the model, and to handle sparse and unbalanced data (quite frequent with animal data). However, allometric scaling using NONMEM is not applicable in all cases. Some of the reasons for failure arise from the differences in enzyme or transporter activities or in metabolic pathways across the species tested.

11.3 PREDICTION OF HUMAN PHARMACOKINETICS USING CELL MODELS

The human body consists of heterogeneous organs that differ in phospholipid contents, organelle densities, and macromolecule distribution patterns. Enhanced distribution to a specific organelle in the target tissue helps to improve the efficacy while undesired accumulation in a subcellular organelle is usually associated with adverse effects

[52–54]. Many of the newly developed drug molecules are inhibitors or stimulators of subcellular enzymes, receptors, or other targets. The subcellular distribution of these drugs in a target tissue is an important determinant of their efficacy or adverse effects. For example, the mechanism of highly active antiretroviral (ARV) therapy through the blockade of different steps of the retrovirus life cycle is now well established. The nucleoside reverse transcriptase inhibitors (NRTIs), integrase inhibitors, and protease inhibitors (PIs) all act on intracellular targets, and the intracellular drug concentrations are closely correlated to the efficacy and toxicity of ARV drugs [55]. The mitochondria and lysosomes are membrane-bound organelles common to virtually all types of eukaryotic cells. Mitochondria-selective accumulation of certain cationic lipophilic drugs accounts for drug retention in target organs as well as a favorable pharmacological profile in preclinical studies. Lysosomal trapping comprises a large portion of total drug uptake of psychotropic drugs, resulting in a more profound drug uptake in lysosome-rich tissues. For therapeutic proteins and monoclonal antibodies, lysosomal degradation is an important elimination pathway following receptor-mediated endocytosis or nonspecific pinocytosis.

The subcellular distribution of a drug molecule may be estimated to some extent by physicochemical properties and unique organellar characteristics (e.g., membrane potential, intraorganellar acidity, bimolecular composition, and organelle density). In recent years, cell-based physiological models have been developed to help enhance our ability to incorporate the subcellular accumulation/degradation of drug molecules into PK and pharmacodynamic (PD) modeling, and this type of modeling is discussed in this section.

11.3.1 Drug Distribution in Lysosomes

Lysosomes (and endosomes) form a complex intracellular recycling system in all nucleated cells, with relatively high abundance in liver, kidney, spleen, and in certain types of cells in the lung [56]. They are characterized by acidic luminal pH (between pH 5 and 6) and a variety of hydrolases (e.g., glucosidases, lipases, proteases, and nucleases) capable of degrading biomolecules and are involved in the normal turnover of organelles [57]. Morphologically, lysosomes and endosomes generally appear as membrane-delimited spheres but can be elongated tubules in fibroblasts [58] and macrophages [59]. The size and number of lysosomes (and endosomes) are maintained by strict regulation of fusion and biogenesis to keep the cellular complement of lysosomes at a relative constant level. Basic amines and weak bases often have a high volume of distribution resulting from their accumulation in the acidic compartments in the cell, usually the lysosomes [60].

Drug-induced lysosomal swelling can be detected in mammalian cells *in vitro* when incubated with high concentration of lysosomotropic compounds, and large swollen vacuoles can often be identified under electron microscopy, laser scanning microscopy, or fluorescent microscopy (Fig. 11.7a–c). Accumulation of lysosomotropic compounds in the lysosomes is also observed *in vivo* in various tissues including liver, kidney, and lung, with the process spanning several weeks [61–63]. There are over 50 marketed pharmaceuticals that induce lysosomal swelling, and they are all weak bases. Several prescribed drugs, amiodarone, azithromycin, chlorpromazine, gentamicin, imipramine, propranolol, and, most notable of all, chloroquine (CQ) are known to cause lysosomal swelling and severe organ impairment in animals and humans [64–66]. CQ, an

Figure 11.7 Chloroquine (CQ)-induced lysosomal swelling and bafilomycin-inhibited CQ uptake in Madin–Darby canine kidney (MDCK) cells. (a) The swollen lysosomes in cells treated with 50 μM CQ for 4 h, as illustrated by vital staining with 0.5 μM LysoTracker® Green (Molecular Probes, L7526) for 30 min. (b) In cells cotreated with 50 μM CQ and 10 nM bafilomycin A1 for 4 h, lysosomal swelling was inhibited. (c) Intracellular CQ accumulation was inhibited by cotreatment with 10 nM bafilomycin A1.

antimalaria medicine, also known as an *inhibitor of autophagic proteolysis*, inhibits the acidification of lysosomes and endosomes leading to disruption of lysosomal function that impairs maturation of viruses. This mechanism is closely associated with CQ's inhibition effects on human immunodeficiency virus (HIV) and hepatitis C virus (HCV) replication by targeting virus-associated autophagy [67].

A lysosomal trapping model has been developed [68] to describe the dynamic process of lysosomal accumulation induced by basic compounds (Fig. 11.8). In brief, assuming constant pH in the lysosomes and minimum permeability of a protonated molecule, the lysosomal to cytosol concentration ratio (F) of a lysosomotropic compound can be estimated as

$$F = \frac{H_i}{H_e} \quad \text{for monobasic drugs}$$

$$F = \left(\frac{H_i}{H_e} \right)^2 \quad \text{for dibasic drugs}$$

where H_i and H_e are the concentrations of hydrogen ion in the lysosome and the extracellular medium, respectively [56]. Assuming that the intralysosomal pH is 5 and the extracellular pH is 7.2, the F value for a dibasic drug such as CQ ($pK_{a,1} = 10.0$, $pK_{a,2} = 7.5$) can be estimated and appears very high (2.5×10^4). Thus, basic drugs may exhibit a pK_a -dependent accumulation in the lysosomes in cell culture or *in vivo* in lysosome-rich tissues, and this is supported by research from several groups. In an experiment from Orton *et al.* [69], the basic compounds with $pK_a > 8.5$ accumulated extensively in the perfused lung, while amines with $pK_a < 7.0$ showed no sign of accumulation. In a lung perfusion experiment by Anderson *et al.* [70], a pK_a -dependent decrease in replacing amphetamine by other basic drugs was reported. Ishizaki *et al.* [71] discovered a significant reduction of tissue to blood ratio (K_p)

Figure 11.8 Mechanism of lysosomal trapping. Basic drugs in their neutral form may diffuse through the plasma and lysosomal membranes and are then protonated in the acidic lysosomal lumen. These molecules are trapped in the lysosomes due to the poor permeability of the charged form. The lysosomal to extracellular concentration ratio F could be roughly estimated as $F = H_l/H_e$ for a monobasic or $F = (H_l/H_e)^2$ for a dibasic compound, where H_l and H_e are concentrations of hydrogen ion in the lysosome and the extracellular medium, respectively [54,66].

of biperiden and trihexyphenidyl in rat lung, heart, and kidney in the presence of ammonium chloride, a compound that abolishes the pH gradient across lysosomal membranes. They also found a strong positive correlation between lysosomal density and the reduction of K_p caused by ammonium chloride, suggesting an important contribution by lysosomes to the total tissue uptake of both drugs. Similar findings were reported by Hayeshi and collaborators [72] with a significant reduction of intracellular uptake of amodiaquine (a weak base drug) in Caco-2 cells in the presence of the basic compounds CQ and ammonium chloride, both induced an increase of intralysosomal pH.

Lysosomal accumulation significantly affects drug distribution in tissues and organs that contain cells with different lysosomal structures and densities. For example, structural integrity of the lysosomal compartment is required for the uptake of CQ in different tissues [73]. In the mammalian central nervous system, the neuron, astroglia, and oligodendroglia cells form the gray and white matter of the brain. In general, the neuronal cells are highly concentrated in the gray matter, while more glial cells are found in the white matter. Studies in the literature suggested a higher lysosomal density in the neuronal cells (i.e., the gray matter) than in the astroglia and oligodendroglia cells (i.e., the white matter) [74,75]. Daniel *et al.* [76] tested a variety of basic psychotropic drugs and measured the tissue uptake by vertically cut brain slices and cellular uptake by primary neuronal and glial cell cultures. They reported that the steady-state uptake of these psychotropic drugs was more pronounced in the neuronal cells (i.e., gray matter) than in the glial cells (i.e., white matter). In the tissue slices or cell culture experiments, the uptake of these drugs was inhibited by ammonium chloride, a weak base interrupting lysosomal luminal acidity, and the inhibitory effect was more prominent in the neuronal than in the glial cells.

As cited above, basic psychotropic drugs tend to accumulate in the acidic subcellular compartment (i.e., lysosomes), and the accumulation of these drugs in the lysosomes could result in an increase in the intralysosomal pH. A positive correlation was reported between the extent of lysosomal trapping and the therapeutic efficacy of those drugs. In addition, several biochemical processes associated with these pharmacological activities were found altered at enhanced intralysosomal pH [77]. For drugs that function by binding to neurotransmitter receptors and/or transporters, the replacement of a less lysosomotropic compound with a more lysosomotropic psychotropic drug would enhance drug efficacy via distributive interaction with lysosomes [78].

11.3.2 Mitochondrial Sequestration of Drug Molecules

Mitochondria are the energy generators in eukaryotic cells, converting oxygen and nutrients into ATP via aerobic respiration. They appear rod shaped under electron microscopy but form a mobile tubular network *in vivo*. Perhaps, as a result of their prokaryotic origin, mitochondria have two functionally distinct membranes with high lipid and protein composition, as well as an independent genome that codes for a variety of inner membrane proteins [79]. The importance of this organelle is confirmed by an increasing number of diseases associated with the mutation of the mitochondrial genome, malfunction of the respiration pathway, and deregulation of the apoptotic machinery [80–85].

Molecules that exert pharmacological effects via accumulation in the mitochondria or by interaction with mitochondrial proteins represent a structurally diversified group. Among these, lipophilic compounds with delocalized positive charges constitute the largest subgroup with selective mitochondrial accumulation because of the highly negative mitochondrial membrane potential [86]. These molecules can diffuse through lipid bilayers because of their high lipophilicity and are driven into the mitochondrial matrix by the membrane potential gradient [87] (Fig. 11.9). Basic amines can be attracted to mitochondria by the electrical potential and can accumulate in this subcellular organelle; however, the selectivity is relatively low unless specific binding to mitochondrial phospholipids occurs [88–90].

Selective mitochondria-tropic molecules may have applications in anticancer therapy because the mitochondrial membrane potential is notably lower in carcinoma cells than in normal epithelial cells. Therefore, lipophilic cation compounds (mitochondria-tropic) may highly concentrate in carcinoma cells and stimulate an anticancer effect. Chen *et al.* investigated the anticarcinoma activity of two lipophilic cations, dequalinium and MKT-007 [92,93] (Fig. 11.10), and found that both compounds could inhibit the growth of human breast carcinoma cells *in vitro* in a clonogenic assay and prolong the survival rate in mice implanted with tumors. Fluorescent microscope studies further confirmed the selective mitochondrial localization of these two compounds and their toxic effect on mitochondria morphology.

In the field of rational drug design, a series of selective mitochondria-targeted prodrugs have been synthesized by adding a lipophilic cation [e.g., triphenyl phosphonium (TPP)] to the drug molecule (Fig. 11.11) [94–100]. For example, Smith *et al.* [101] covalently attached the TPP cation to the natural antioxidant coenzyme Q to form a prodrug. After oral administration, this mitochondria-targeted coenzyme Q (MitoQ) was rapidly taken up by tissues that are severely affected by mitochondrial dysfunction (the heart, liver, brain, and skeletal muscle), reaching a very high (several hundredfold

Figure 11.9 Mechanism of mitochondrial selectivity. Driven by electropotential across the membrane, a lipophilic cationic molecule will cross the phospholipid bilayers toward the negatively charged mitochondria lumen. The extent of accumulation can be described by the Nernst equation: $E_{\text{out}} - E_{\text{in}} = \frac{RT}{zF} \ln \frac{[\text{ion}]_{\text{in}}}{[\text{ion}]_{\text{out}}}$, where E is the membrane potential in volt, R is the universal gas constant, T is the absolute temperature, z is the number of positive charge of the ion, F is the Faraday constant, and $[\text{ion}]$ is the concentration of the ion. Assuming a negative mitochondrial membrane potential of 180 mV at 37°C [91] and a negative plasma membrane potential of 10 mV compared to the cytosol, a positively charged mono-ion may accumulate in the mitochondria with a concentration approximately 10^2 - to 10^3 -fold higher than that in the extracellular environment [89,90].

Figure 11.10 Two representative mitochondria-selective lipophilic compounds with delocalized charge(s).

higher) concentration in the mitochondria of these tissues. Meanwhile, the MitoQ was timely cleared from other tissues in the body, leaving no systemic adverse effects. It was also reported that the MitoQ prodrug protected rats from heart dysfunction and cell death caused by ischemia-reperfusion [102], decreased inflammatory response in a rat model with sepsis [103], maintained mitochondrial membrane potential against fluoroquinolone-induced oxidative stress [104], and reduced systolic blood pressure and cardiac hypertrophy in stroke-prone spontaneously hypertensive rats [105]. The synthesis and characteristics of TPP-conjugated antioxidants have been reviewed by Smith and Murphy [106,107].

Figure 11.11 Lipophilic molecules with delocalized positive charges targeted to the mitochondria by conjugation to triphenyl phosphonium.

11.3.3 Binding of Drugs to DNA and Other Nonorganelle Components

The cellular composition of proteins, DNA, and phospholipids in plasma, liver, heart, lung, kidney, and many other tissues varies in response to dietary and disease conditions [108]. This could cause high variation in drug–protein (or drug–DNA, drug–phospholipid) interaction in different tissues and affect the disposition, PK, and PD of drug molecules. For example, Nishiura and collaborators [109] revealed that the phosphatidylserine (PhS) content is much higher in the nucleus and membrane fractions than in other organelles in the lung. If a drug molecule preferentially binds to a specific type of lipid component in a subcellular organelle in the tissue, the distribution pattern of this drug may highly correlate with the lipid composition in that organelle. Murata *et al.* [110] reported that the distribution volume of grepafloxacin (GPFX), a quinolone antibacterial agent, is much higher than that of other quinolone antibacterials such as ofloxacin. Suzuki *et al.* have conducted additional studies [111] and identified a positive correlation between the amount of GPFX in subcellular fractions and the PhS content in these fractions (Fig. 11.12). Many anticancer drugs act by interacting with DNA and blocking the biosynthesis of macromolecules. Terasaki *et al.* [112] investigated the tissue distribution of doxorubicin in rats and rabbits and demonstrated a close correlation between tissue uptake of doxorubicin and the levels of DNA in the tissue. Additional studies confirmed the exclusive subcellular localization of doxorubicin associated with the nucleus and a weak correlation between doxorubicin concentration and lipid components. A similar correlation between DNA binding and tissue distribution has also been reported for doxorubicin analogs daunomycin, adriamycinol, daunorubicinol, and actinomycin D [113].

11.3.4 Cell-Based Pharmacokinetic Modeling to Predict the Absorption and Disposition Kinetics in Humans

PBPK models are developed with a series of organ/tissue spaces arranged in a flow diagram incorporating anatomical, physiological, and drug-specific parameters into the model. The whole-body PBPK modeling could help us to predict the kinetic profiles in plasma and in any tissues associated with pharmacological activity or toxicity,

Figure 11.12 Phospholipids composition and subcellular distribution of grepafloxacin (GPFx) in the lung. The contents of phosphatidylserine (PhS) in different subcellular fractions were measured [107] and plotted against the fraction of GPFx discovered in the corresponding subcellular fraction [109]. The majority of GPFx was distributed in the nucleus and plasma membrane fraction (60.3%), followed by the lysosome and mitochondria fraction (22.7%) and the microsome fraction (12.9%). The distribution of GPFx showed good correlation with PhS contents in these subcellular fractions.

and it is a valuable tool to assist the extrapolation of PK/PD information from animals to humans and in decision making in pharmaceutical research and development [114–116]. As discussed previously, the disposition of a drug molecule in the body is controlled by a variety of factors: (i) the organ blood flow and size, (ii) membrane permeability and the physicochemical properties of a drug molecule, and (iii) the binding affinity of the molecule to the plasma/tissue proteins, membrane transporters, and the cytosol/subcellular organelles. Physiologically realistic CBPK models have been developed in recent years to incorporate all these factors in the modeling, and several examples are listed in Tables 11.8 and 11.9. A representative whole-body PBPK model incorporating cell-based mechanism is presented in Fig. 11.13 correlating the cellular events with the disposition of a drug molecule in the body. Single-cell-based pharmacokinetic models were developed in 2005–2008 to simultaneously predict passive transcellular permeability and subcellular distribution of small molecules in polarized epithelial cells [117–119], and one example is presented below. This model consists of several compartments [cellular (cytosol, mitochondria, lysosomes) and extracellular (apical and basolateral)] as described in Equations 11.1–11.4:

$$\frac{dm_c}{dt} = A_a J_{a,c} - A_m J_{c,m} - A_l J_{c,l} - A_b J_{c,b} \quad (11.1)$$

$$\frac{dm_m}{dt} = A_m J_{c,m} \quad (11.2)$$

$$\frac{dm_l}{dt} = A_l J_{c,l} \quad (11.3)$$

$$\frac{dm_b}{dt} = A_b J_{c,b} \quad (11.4)$$

TABLE 11.8 Molecular Characteristics and Drugs with Subcellular Accumulation or Binding

Subcellular Organelles		Distribution	Drugs with Subcellular Accumulation or Binding	Molecular Properties	Mechanisms Involved
Lysosomes		High abundance in liver, kidney, spleen, and some types of cells in the lung [56]	Amiodarone, azithromycin, chlorpromazine, gentamicin, imipramine, propranolol, biperiden, trihexyphenidyl, and chloroquine [62–64]	Weak bases (including some moderate to strong basic compounds)	Ion trapping, electrostatic interactions
Mitochondria		High abundance in muscle	Dequalinium, MKT-007, TPP-conjugated molecules, such as MitoQ [89,90, 92–99]	Lipophilic cations	Passive diffusion, and highly negative mitochondrial membrane potential
Nonorganellar component	DNA	All tissues	Doxorubicin, daunomycin, adriamycinol, daunorubicinol, actinomycin D, [112,113]	Positively charged at physiological pH	Electrostatic interaction
	Lipids	High abundance in adipose [124]	Lipophilic molecules	Lipophilic	Partitioning or electrostatic interaction

TABLE 11.9 Examples of Cell-Based PBPK Models and Application in PK Prediction

Compound	Model Features	References
Napsagatran	Permeability-limited distribution was assumed in the liver; active transport parameters were obtained from <i>in vitro</i> hepatocyte experiment, and passive diffusion was negligible based on hepatocyte data; transport proteins involved are still unknown; biliary excretion rate was estimated from bile-duct-cannulated rats.	123
Fexofenadine	Permeability-limited distribution assumed in the liver; active transport parameters were obtained from <i>in vitro</i> hepatocyte experiment, and medium passive diffusion was derived from hepatocyte data; it is a substrate of Oatp1a1 and 1a4 (hepatic uptake), Mrp3 (hepatic efflux), Mdr1 and Abcc11 (biliary excretion); biliary excretion rate was estimated from bile-duct-cannulated rats.	123
A variety of bases, acids, neutrals, and zwitterions	Passive diffusion and steady state were assumed; binding to plasma protein, partitioning between neutral and ionic species and neutral lipid, neutral phospholipids, and acidic phospholipids were considered in all major tissues.	124,125
A variety of monovalent molecules	Passive diffusion was assumed; Fick's First Law and Nernst–Planck equation were applied to model the transport of neutral and ionic species across biomembrane. Subcellular accumulation and transcellular permeability of small molecules can be calculated.	117,118
Pravastatin	Active transport with organic anion-transporting polypeptide (OATP) 1B1 and multidrug-resistance-associated protein (MRP) 2 included	126
Methotrexate	Model features permeability-limited compartment for bone marrow, GI tract, spleen, liver, kidney, muscle, and skin; extracellular and intracellular binding were included for those tissues. Permeability-limited tumor compartment was included in a later model.	127,128
SDZ IMM 125	Cell-based PBPK model with three major components: (i) vascular blood cells, (ii) combined interstitial and tissue plasma space, and (iii) tissue cells (rapidly interacting pool and moderately interacting pool).	129
Cyclosporine A	Model features nonlinear intracellular binding and tissue distribution.	130,131
Terbinafine	Cell-based PBPK model with permeability-limited distribution in skin and testis.	132
Fingolimod (FTY720)	Cell-based PBPK model with permeability-limited distribution in brain, thymus, and lymph nodes.	133

Everolimus (RAD001)	Cell-based PBPK model with nonlinear partitioning into red blood cells, nonlinear tissue binding, and degradation in plasma.	120
ISIS 1082	Cell-based PBPK model with permeability-limited distribution in tissues.	134
Domperidone	P-gp-mediated efflux was explored in mouse brain and heart.	135
β -Endorphin	Cell-based PBPK model with capillary-membrane-limited distribution in lung, heart, muscle, skin, liver, gut, kidney, brain, and adipose.	136
Monoclonal antibodies	Cell-based PBPK model with lymph circulation. Two-pore model was employed for capillary-membrane-limited step. Binding components were added and specified for different mAbs.	91,137

Figure 11.13 Cell-based PBPK modeling and application to human PK/PD prediction. The anatomical/physiological [e.g., size and blood flow (Q) for each tissue] and drug-specific parameters (e.g., ionization, lipophilicity, number of hydrogen bonds, molecular size, polar surface area, red blood cell partitioning, binding to proteins, DNA, and other subcellular components) are incorporated into the model. RBC, red blood cell; Lyso, lysosome; Mito, mitochondria; RTC, representative tissue cell.

where J is the net flux, m is the total molecular mass, t is time, A is membrane surface area, and the subscripts c, m, l, a, and b represent the cytosol, mitochondria, lysosomes, and extracellular (apical and basolateral), respectively. The concentration in the apical (donor) is assumed to be constant, and the concentration in the basolateral (receiver) compartment is kept at sink condition. The passive diffusion of neutral molecules across the membranes is described by Fick's First Law along the concentration gradient (C_o or C_i) as listed in Equation (11.5):

$$J = P_m(C_o - C_i) \quad (11.5)$$

where P_m is the permeability of the molecules across the cellular membrane.

For electrolytes, the driving force across cellular membrane may be the differences in electrochemical gradient (described by the Nernst–Planck equation). Assuming trans-membrane electrical potential to be constant along the membrane, the flux of an ionic

molecule across the membrane is expressed by Equation (11.6);

$$J = -D \left[\frac{dC(x)}{dx} + C(x) \left(\frac{zF}{RT} \right) \left(\frac{E}{d} \right) \right] \quad (11.6)$$

where D is the diffusion coefficient (area per time unit); F , R , T , and z are the Faraday constant, molar gas constant, temperature (in Kelvin), and electric charge, respectively; E and d are the membrane potential and thickness, respectively; and $C(x)$ is the concentration of the drug molecule. Equation (11.7) is then derived by integrating Equation (11.6) from 0 to d for x ,

$$J = P \frac{N}{e^N - 1} (C_o - C_i e^N) \quad (11.7)$$

where $P = D/d$ (diffusion coefficient/membrane thickness) and $N = zEF/RT$.

Several other CBPK models have been developed to include subcellular binding (e.g., the binding to tubulins/microtubules) [141–143], the efflux and uptake membrane transporters [e.g., P-glycoproteins (P-gps)], and the hepatic metabolic CL as listed in Table 11.9. For example, paclitaxel's cytotoxicity is closely related to its binding to subcellular tubulins, and a CBPK model was developed based on experiments using human breast MCF7 tumor cells with negligible P-gp expression and human breast carcinoma BC19 cells derived from *mdr1* (i.e., P-gp) transfected MCF7 cells [142]. The outcome from the model analysis indicates that the P-gp-mediated drug efflux accounts for more than 70% of total drug efflux when the extracellular drug concentrations are lower than 200 nM, but the efflux accounts for less than 30% of total efflux when the extracellular drug concentration is 1000 nM. These findings suggest that if patients have P-gp expression in the tumor similar to those in the BC19 cells, the effect of P-gp-mediated drug efflux may not be significant since clinically relevant concentrations are generally higher than 200 nM.

Poirier *et al.* [144] reported a mechanism-based model including active uptake [e.g., via organic anion-transporting peptide (OATP)], nonspecific binding, and saturable hepatic metabolism. Compared to the conventional two-step approach, the CBPK model greatly improved the estimation accuracy and precision of hepatic metabolic CL.

The elimination of pravastatin is mediated by OATP and the multidrug-resistance-associated protein 2 (MRP2), while the pharmacological activities and the side effects are associated with the hepatic disposition kinetics and/or nonspecific accumulation in the muscle and brain tissues. A perfusion limited cell-based PBPK model was developed by Watanabe *et al.* to predict the exposure of pravastatin in plasma, liver, muscle, and brain by integrating data from both *in vitro* and *in vivo* experiments into the model (e.g., active uptake by multiple transporters, hepatic metabolic CL, active biliary excretion) [126]. The liver was segmented into five subcomponents, each consisting of extracellular and hepatocyte compartments. Overall, the cell-based PBPK model gave reasonable predictions, and the model-predicted kinetic profiles of pravastatin in the plasma and tissues were highly correlated with the observed values in rats and humans [126].

In summary, many important biological events at the cellular levels may affect the disposition of drug molecules in the organ/tissue and the whole body. CBPK models may be linked to whole-body PBPK models to predict the effects of cellular events on drug absorption and disposition.

11.4 CONCLUSIONS AND FUTURE PERSPECTIVES

The ability to predict the PK properties (i.e., CL, volume of distribution, elimination half-life, bioavailability, concentration–time profile) during early discovery and development is of great significance for both small-molecule and protein drugs. The interspecies scaling based on animal data and the allometric relationship between body size and biological function is a useful tool widely used in the pharmaceutical industry for this type of projection. The SA method has been successfully applied to the estimation of human CL and volume of distribution for many small- and macromolecule drugs. However, for small-molecule drugs with complicated oxidative metabolic pathway and significant cross-species differences in hepatic metabolism, the SA power equation may not work well for the estimation of human CL, and correction factors (e.g., MLP, BRW, LBF, *in vitro* metabolic CL, free fraction in blood, binding affinity to receptors or subcellular components) have been proposed to enhance the accuracy of prediction. Each of these techniques mentioned above has its own merits and drawbacks, and some of them have had only partial success in predicting human CL. Research work using *in vitro*, *in vivo*, and *in silico* models are still ongoing to further improve the estimation accuracy of human PK profiles to help reduce the risk and the tremendous financial costs associated with failed clinical trials. Cross-species differences in plasma protein binding is another potential problem in interspecies scaling because only the unbound drug molecules are filtered and secreted in the kidney or metabolized and eliminated in the liver. Literature published in this area has demonstrated that human CL would be more accurately predicted using unbound plasma CL. However, accurate measurement of the free fraction (f_u) in plasma or blood is critical especially for drugs highly bound to plasma proteins. Experimental error in f_u estimation could compromise the scaling results.

Recent advances in computational chemistry have provided additional tools (i) to calculate molecular descriptors (e.g., Log P , Log D , polar surface area and other polar descriptors, free rotatable bonds, atomic charge or free energy associated parameters) to help improve the projection accuracy of the absorption, elimination, and target tissue distribution of drug molecules in humans and (ii) to facilitate the development of cell-based PK/PD models to identify the mechanism associated with biological membrane penetration and drug-receptor/enzyme interaction. For example, high correlation has been reported between the polar surface area (PSA) of a drug molecule and the fraction absorbed in humans [145], or between the PSA and the distribution to brain tissue [146]. Biological mechanism-based models (e.g., PBPK or CBPK models) allow separation of biological and compound-specific components and are thus, by design, capable of integrating information from various processes. By using measurable physiological, anatomical, and biochemical parameters (e.g., organ volume, blood flow rate, binding affinity, and biomembrane permeability), the PBPK or CBPK models can successfully predict the concentration–time profiles in the blood and tissues associated with safety or efficacy in humans [120,121,134,122,147]. The power and utility of PBPK or CBPK models is further increased when linked with mechanistically based PD models [138,148,139,149]. This effective combination is shifting the endpoint of modeling/simulation from a concentration versus time curve toward the time course of a PD outcome. Use of such models can have a major impact during all phases of drug discovery and development and may ultimately result in significant cost reductions for the pharmaceutical industry. In addition, mechanistically based models are

valuable tools for hypothesis testing and mechanistic understanding of the compound's properties and could provide an opportunity to make uncertainty and variability more transparent. With the availability of these models at the preclinical stage, early estimates of the PK/PD profiles in the relevant target (human) population can be obtained to reduce the uncertainty and to improve decision making at early drug discovery and development. This type of combined PBPK/PD or CBPK/PD assessment could provide critical information on the efficacy and safety of drug candidates *in vivo* and bridge the PK/PD concept established during the preclinical development to clinical phase I–III trials. In summary, additional research and investigation are in progress to help increase our ability in performing interspecies scaling and the projection of PK and PD to humans. We believe that the advantage of these newly developed computational models will gradually be recognized and that they will be widely utilized in early drug discovery and development.

12.1 INTRODUCTION

Investigations pertaining to profiling the pharmacokinetics (PK) of a drug, require that a drug dose be administered either intra- or extravascularly, followed by measurement of blood, plasma, or serum drug concentrations to follow and mathematically model the fate of the drug. Following drug administration, the drug finds itself directly in the systemic circulation (intravascular dosing) or has to reach the systemic circulation via the process of absorption (extra-vascular administration). The drug then undergoes the process of distribution (defined as the reversible transfer of drug from and to the systemic circulation) that results in the drug reaching the sites of action, the sites of adverse effects, and the organs of elimination. Biotransformation or excretion by the organs of elimination subsequently leads to the loss of drug from the system and the termination of biological activity [1,2].

The drug in the systemic circulation can interact with many of the components of the blood and likewise may also interact with non-target components in the tissues. These interactions generally involve reversible binding to blood or tissue proteins mediated by noncovalent interactions that include ionic, electrostatic, hydrophobic, and van der Waals forces [1,3]. The consequence of these interactions is increase in the apparent

molecular mass and molecular size of the bound drug. This leads to the inability of the complex (or drug) to permeate across membranes by simple diffusion or by glomerular filtration thereby affecting the rate and extent of drug distribution and renal excretion. Furthermore, these interactions also result in an inability to enter the active site of the target and/or drug-metabolizing enzymes thus impacting the pharmacological activity and/or the first-pass or systemic elimination or clearance of the drug.

The components involved in these interactions in the blood are plasma proteins and include human serum albumin (HSA), alpha acid glycoprotein (AAG), globulins (α , β , and γ), lipoproteins [including chylomicrons, very low density lipoproteins (VLDLs), low density lipoproteins (LDLs), high density lipoproteins (HDLs), and other related forms of lipoproteins), transcortin, to name a few [3]. In addition, the drug may also be sequestered in blood cells such as erythrocytes, leucocytes, and platelets. Binding of drugs can also occur to tissue proteins and result in differential nonhomogenous distribution of drug within and among tissues [1,3].

Among all of the interactions listed, the interaction with plasma proteins has arguably the maximum impact on both the PK and the pharmacodynamics of drugs, in addition to the very specific binding to the target molecule involved in drug action. HSA and AAG, in this regard, have a greater impact on plasma protein binding than other plasma components. HSA is a single polypeptide chain with a molecular mass of about 66 kDa (585 amino acids). HSA is present in plasma at concentrations as high as 50 mg/mL (about 700 μ M). It is known that HSA has six different types of binding sites that have been delineated based on the binding properties. For example, type I and II sites (present up to three times on an HSA molecule) bind warfarin and diazepam, respectively. Similarly, type III site (present at six or more regions on an HSA molecule) binds phenytoin in an apparently nonsaturable manner. Some of other drugs known to bind to HSA are NSAIDs (nonsteroidal anti-inflammatory drugs), digoxin, imipramine, theophylline, caffeine, probenecid, tamoxifen, and so on [1,3,4]. Both the high concentrations in the plasma and the presence of a multitude of binding sites make HSA the most versatile of proteins that bind drugs. AAG is a single polypeptide with a molecular mass of 44 kDa and present in the plasma in concentrations up to 1–2 mg/mL (45 μ M). AAG is generally known to have high affinity for basic drugs such as imipramine and propranolol. Other proteins that are present in lower concentration in the plasma have much lower significance in terms of the impact on the PK of the drug.

The drug–protein binding phenomenon is most commonly characterized by fraction of drug unbound (f_u) (or referred to as the free fraction) in plasma or tissue and by the dissociation rate constant (K_s) that is indicative of the strength of the binding [1–4]. For a drug (D) and protein (P), the interaction is depicted below

where k_1 and k_{-1} are the rate constants associated with the formation and breakdown of the DP complex. At equilibrium,

$$k_1[D_f][P_f] = k_{-1}[DP]$$

The dissociation constant (K_s) may be defined as follows:

$$K_s = \frac{k_{-1}}{k_1} = \frac{[D_f][P_f]}{[DP]}$$

$$[DP] = \frac{[D_f]P_f}{K_s}$$

By applying law of mass action that the total drug concentration $[D]$ is the sum of $[D_f] + [DP]$ and that the free fraction of the drug is defined as the relative concentration of free to the total concentration of the drug,

$$f_u = \frac{\text{Free drug concentration}}{\text{Total drug concentration}} = \frac{[D_f]}{[D]} = \frac{[D_f]}{[D_f] + [DP]}$$

Therefore,

$$f_u = \frac{[D_f]}{\left([D_f] + \frac{[D_f][P_f]}{K_s}\right)}$$

Dividing the numerator and denominator by $[D_f]$,

$$f_u = \frac{1}{\left(1 + \frac{[P_f]}{K_s}\right)} = \frac{K_s}{K_s + [P_f]}$$

This indicates that the fraction unbound (free fraction) is directly proportional to the dissociation rate constant. The higher the tendency of the DP complex to dissociate to release free drug, the higher will be the fraction unbound. The fraction unbound is also inversely related to the free protein concentration, in that more the concentration of free protein, the lower will be the value of fraction unbound. The unbound fraction may be expressed as values ranging from 0 to 1 or as a percentage ranging from 0% to 100%. In general, drugs with a f_u of 0.9 (90%) or more are referred to as *highly protein-bound drugs*. Although, not explicitly indicated, f_u is also dependent on the total drug concentration and in situations where the dissociation constant is small (less free drug concentration) and the plasma total drug concentrations are high, the binding sites on the protein may be saturated and f_u may increase. However, for most drugs, the f_u is essentially constant over the therapeutic drug concentration range.

Since it is only the free or unbound drug that is able to cross membranes and interact with the target tissues, distribution equilibrium is achieved when the free concentrations in both the plasma and tissue are identical. However, at this juncture, the total concentrations of drug in the plasma and tissues may be nonidentical. For example, if the fraction unbound in the plasma is 0.9 (unbound concentration of 9 units relative to a total concentration of 10 units) and that in the tissue is 0.1 (unbound concentration of 9 units relative to a total concentration of 90 units), one can appreciate that at distribution equilibrium when the free concentrations of drug are same and equal to 9 units in both the plasma and tissue, the total tissue concentration is ninefold higher. A reversal of this situation can result in plasma concentrations being ninefold higher than tissue concentrations. In general, lower the free fraction in the plasma, less is the propensity for the drug to go to tissue compartments. The primary PK parameter that

reflects this interplay is the apparent volume of distribution (V) [1,2]. The equation that states this relationship is

$$V = V_p + V_{TW} \left(\frac{f_u}{f_{uT}} \right)$$

where V_p and V_{TW} are the plasma and tissue water volumes, respectively, and f_u and f_{uT} are the fraction of drug unbound in the plasma and tissue water, respectively.

Thus, other factors being equal, drugs that have a lower free fraction in plasma tend to be sequestered in the plasma compartment (showing a low V) relative to drugs with a higher free fraction in plasma. Likewise, drugs that have a lower free fraction in tissues tend to be sequestered in the tissue compartment (showing a high V) relative to drugs with a higher free fraction in tissue.

The free drug is also the entity that is amenable to metabolism by drug-metabolizing enzymes, glomerular filtration, active secretion and active reabsorption.

The determinants of the organ metabolic clearance [1–4] are indicated by the following equation.

$$CL_{org} = \frac{Q_{b,org} \times f_{u,b} \times CL_{int}}{Q_{b,org} + [f_{u,b} \times CL_{int}]}$$

where CL_{org} and CL_{int} are organ clearance and intrinsic clearance (volume/time), Q_{org} is the organ perfusion rate or organ blood flow (volume/time) and $f_{u,b}$ is fraction unbound in blood.

For drugs that are efficiently metabolized by drug-metabolizing enzymes and have high intrinsic clearance values, the above equation collapses to the following:

$$CL_{org} = \frac{Q_{b,org} \times f_{u,b} \times CL_{int}}{f_{u,b} \times CL_{int}}$$

$$CL_{org} = Q_{b,org}$$

The organ clearance is thus perfusion rate limited and independent of both protein binding and intrinsic clearance.

For drugs that are not good substrates for drug-metabolizing enzymes (low intrinsic clearance), the equation for organ metabolic clearance then rearranges to the following:

$$CL_{org} = \frac{Q_{b,org} \times f_{u,b} \times CL_{int}}{Q_{b,org}}$$

$$CL_{org} = f_{u,b} \times CL_{int}$$

The free fraction in blood or $f_{u,b}$ is now a crucial determinant of hepatic metabolic clearance in addition to the low intrinsic capacity (intrinsic clearance) of drug-metabolizing enzymes that can biotransform the drug.

As an extension, organ clearance can also be expressed as

$$CL_{org} = Q_{b,org} \times ER$$

where ER is the extraction ratio and is the fraction of drug that is removed by the eliminating organ per single pass of the blood through the organ [1,2,4]. As a corollary,

the fraction that escapes the elimination organ is given by $[1 - ER]$. This relationship allows one to estimate the expected bioavailability (F) of an orally administered drug.

$$F = f_a \times f_g \times f_h$$

where f_a , f_g , and f_h are fractions that escape the lumen, gut wall metabolism, and hepatic metabolism, respectively. If we assume that all of drug escapes the lumen and gut wall metabolism, f_h will then determine the lower limit of the oral bioavailability. Thus,

$$F = 1 \times 1 \times f_h = f_h$$

But,

$$\begin{aligned} F &= f_h = 1 - ER \\ F &= 1 - \left[\frac{f_{u,b} \times CL_{int}}{Q_{b,org} + (f_{u,b} \times CL_{int})} \right] \\ F &= \frac{Q_{b,org}}{[Q_{b,org} + (f_{u,b} \times CL_{int})]} \end{aligned}$$

For a low clearance drug (low CL_{int}), this equation collapses to

$$F = \frac{Q_{b,org}}{Q_{b,org}} = 1$$

For a high clearance drug (high CL_{int}), this equation collapses to

$$F = \frac{Q_{b,org}}{(f_{u,b} \times CL_{int})}$$

Thus, a higher fraction unbound can lower the overall bioavailability of the drug. Overall, f_u can significantly impact hepatic clearance, oral bioavailability, and total body clearance (CL).

Similarly, the overall filtration clearance of a drug in the kidney is given by $f_u \cdot GFR$ (glomerular filtration rate) [1,2]. Furthermore, active secretion and active reabsorption that are mediated by specific efflux or uptake transporters are also able to accept only unbound drug for transport, and thus, the unbound fraction of drug impacts these processes as well.

To summarize, polytherapy or disease states that alter the drug–plasma and/or drug–tissue binding due to changes in the concentration of the plasma/tissue-binding proteins or displacement of bound drug from its binding sites can result in changes in the plasma free concentrations of the drug and potentially lead to changes in primary PK parameters (V and CL) and consequently the derived PK parameters, such as half-life and AUC, of a victim drug.

During the discovery and development of an NCE (new chemical entity), determination of the plasma protein binding or HSA binding of a NCE is thus crucial to

aid the complete PK profiling of the drug and evaluation of the drug–drug interaction potential of the NCE.

12.2 ESTIMATION OF PROTEIN BINDING

Several *in vitro* methods are used for the estimation of the unbound drug fraction (f_u) [5,6] and include equilibrium dialysis, ultrafiltration, ultracentrifugation, and so on (Fig. 12.1). Among them, equilibrium dialysis and ultrafiltration are most commonly used for the estimation of f_u in plasma, serum, or diluted tissue homogenate because of their simplicity and high throughput compatibility. However, neither of these methods is free of biological, chemical, or physical artifacts, and the advantages and disadvantages of each method are discussed in this section.

Often, in drug discovery and development, the choice of method is based on progress stage of the compound. As the compound progresses in its life cycle, the methods become more robust and reliable (Fig. 12.2). In early drug discovery, rapid screening methods are required, which allow classification of compounds in low, medium, and high binding categories. As the compound moves forward and more quantity is available, more definitive methods such as equilibrium dialysis and ultrafiltration are used, which allow the study of sex or species differences in plasma protein binding, linearity in binding with respect to drug and protein concentration and identification of proteins to which drugs bind. It is recommended that protein binding should be studied by at least two methods for compounds in this stage and the binding estimations are supported by sensitive and specific analytical methods [e.g., liquid chromatography tandem mass spectrometry (LC-MS/MS)]. For compounds in clinical development,

Figure 12.1 Methods used to assess protein binding of drugs. Methods for estimation of plasma protein binding involve either prior separation of bound and unbound drug [bottom right quadrant of the figure] or determination without prior separation of bound drug from free drug [top right quadrant of the figure]. Routine methods use the separation of free and protein-bound drugs for estimation of the fraction unbound.

Figure 12.2 Protein binding methods and their application in various stages of the drug development. The method used to assess protein binding is dependent on the depth of information required. At early stages, quick and semiquantitative estimation of the fraction unbound is sufficient, but during the clinical development phase, an accurate estimate of protein binding is done using equilibrium dialysis—“the gold standard” as it also has the potential for evaluation of protein-binding-based drug–drug interaction.

radiolabeled compounds that provide a more reliable and robust assessment of protein binding are used.

12.2.1 Equilibrium Dialysis

Equilibrium dialysis method is often considered as the “gold standard” for measuring protein binding. It is based on the establishment of an equilibrium state between a protein compartment and a buffer compartment, separated by a semipermeable membrane. This membrane (pore size/molecular weight cutoff (MWCO) is selected depending on the compound to be studied or application *viz.* 12–14K MWCO, 6–8K MWCO, 10K MWCO, 3.5K MWCO, etc.) and allows only low molecular weight ligands such as drug molecules to be transported between two compartments. The experimental method is depicted in Fig. 12.3.

Briefly, drug-spiked biological matrix (plasma, serum, or tissue homogenate) is placed in one compartment and buffer (typically sodium or potassium phosphate buffer, pH 7.4) is placed in the other, and the assembly is incubated at 37 °C until equilibrium between free drug concentration in matrix and that in the buffer is reached (incubation period usually lasts longer than 2 h). During the incubation period, in addition to the

Figure 12.3 Equilibrium dialysis method for estimating protein binding of drugs. The figure indicates the movement of free drug (closed circle) from the left reservoir that contains both free drug and drug bound to protein (open circle), through the semipermeable membrane, to the right reservoir that contains only buffer. At equilibrium, the free drug concentrations on both sides are the same. Note the volume shift due to movement of buffer to the left side protein-containing chamber due to osmotic pressure and/or Donnan ion effect.

transport of unbound drug molecules, water molecules from the buffer compartment are continuously moving to the matrix compartment because of the differences in osmotic pressure between the two compartments and/or the Donnan ion effect. This results in an increase in volume in the matrix compartment and decrease in volume in the buffer compartment; this phenomenon is known as the *volume shift*, which is usually about 15–20% and needs to be corrected during the estimation of protein binding. At equilibrium, aliquots of matrix and buffer are sampled for analysis of drug concentrations. Also volumes in the matrix and buffer compartments are measured. Protein binding is estimated as shown in Equation 12.1.

$$\text{Protein binding (\%)} = \frac{(C_{pe} - C_{be}) \times \frac{V_{pe}}{V_{pi}}}{\left[(C_{pe} - C_{be}) \times \frac{V_{pe}}{V_{pi}} \right] + C_{be}} \quad (12.1)$$

where C_{pe} is the peak area of analyte in matrix at equilibrium, C_{be} the peak area of analyte in buffer at equilibrium, V_{pe} the volume of matrix at equilibrium, and V_{pi} the initial volume of matrix.

Maintenance of physiological pH and temperature is important for accurate estimation of protein binding [7,8]. High throughput equilibrium dialysis apparatus have become increasingly popular and are widely accepted today. These include the Rapid Equilibrium Device (RED, Thermo Scientific) [9], Microequilibrium Dialysis Device HTD 96 (HTDialysis) [10], 96-Well Equilibrium Dialyzer (Harvard Apparatus) [11], and so on. These require shorter preparation and dialysis times and are amenable to automation. For bioanalysis, after attainment of equilibrium, an aliquot of buffer

(90 μL) from the buffer compartment is mixed with blank matrix (10 μL) and similarly, an aliquot of matrix (10 μL) from the matrix compartment is mixed with blank buffer (90 μL) before sample processing. This approach eliminates the need for preparation of separate calibration curves of drug in buffer and matrix and can save valuable analytical instrumentation time. For calculation of protein binding, the values are corrected for sample dilution by applying respective dilution factors, that is, values from matrix side are multiplied by 10 and values from the buffer side are multiplied by 1.1. The fraction of unbound drug (f_u) is calculated as shown in Equation 12.2.

$$f_u = \frac{C_u}{C_b} \quad (12.2)$$

where C_u is the concentration of drug on buffer side and C_b the concentration of drug on matrix side.

The percentages of drug unbound or free and bound to protein are calculated using Equations 12.3 and 12.4.

$$\% \text{ Drug Unbound} = f_u \cdot 100 \quad (12.3)$$

$$\% \text{ Protein binding} = (1 - f_u)100 \quad (12.4)$$

The correction for volume shift is not generally used in the 96-well setup because of the large error associated with withdrawal and measurement of small volumes required for the correction. When nonradiolabeled drug is used, drug concentrations in matrix and buffer are typically analyzed by LC-MS/MS, and when a radiolabeled drug is used, analysis is performed by liquid scintillation counting (LSC).

Equilibrium dialysis can also be used to study the binding interactions by dialyzing free drug through a semipermeable membrane until its concentration across the membrane is at equilibrium (Harvard Apparatus). Data obtained under different experimental conditions can then provide information on various binding parameters such as binding constants and number of binding sites or binding capacity. Binding to HSA and AAG can be studied by this method using purified protein solutions [12].

Equilibrium dialysis is theoretically the most accurate method for determining plasma protein binding because the equilibrium is not shifted when aliquots are taken from either side of the membrane [13]. It is a suitable method for drugs that are highly protein bound (>98%). Some advantages and disadvantages of equilibrium dialysis method are listed in the following.

Advantages

- Easy to setup and use;
- Needs small amount of sample;
- Temperature controlled;
- Thermodynamically sound;
- Reproducible results can be obtained even for low affinity compounds;
- Meaningful results can be determined for compounds with nonspecific binding (NSB) [14];
- Compatible to high throughput with robotic systems;
- Binding interactions can be studied.

Disadvantages

- Requires long time to reach equilibrium;
- Volume shift [15];
- Donnan effects (hindering of the passage of free ligand) [16];
- NSB;
- Potential degradation of compound in matrix due to thermal or metabolic instability;
- Shift of pH due to continuous loss of carbon dioxide [17];
- Overestimation of free fraction as a result of slight leakage of protein into buffer compartment [18].

12.2.2 Ultrafiltration

Ultrafiltration method is based on the separation of unbound drug from the protein-bound drug by filtering the protein–drug matrix through a semipermeable membrane under positive pressure generated by centrifugation. The experimental method is depicted in Fig. 12.4.

Briefly, drug-spiked matrix is placed in the sample reservoir, and the reservoir is capped and fitted onto a sample collection tube. The entire ultrafiltration assembly is then centrifuged at $1000\text{--}2000\times g$. The incubation time is fixed based on the flow rate such that the ultrafiltrate (plasma water, PW) obtained is about one-fifth of the initial volume of the sample. The centrifugation can be carried out at room temperature or at 37°C ; however, the chosen temperature should be maintained constant during the centrifugation process as drug binding decreases with rising temperature. A major

Figure 12.4 Ultrafiltration method for estimating protein binding of drugs. The figure indicates the movement of free drug (closed circle) from the top chamber that contains both free drug and drug bound to protein (open circle), through the ultrafiltration membrane, to the bottom chamber. The movement is assisted by the application of a centrifugal force. The ultrafiltrate is analyzed to obtain the free drug concentration.

drawback of the ultrafiltration method is the potential NSB of the drug to the plastic tube and ultrafiltration membrane, which will lead to an underestimation of the free drug concentration. This is usually assessed and corrected when calculating the protein binding by running a parallel control sample using drug-spiked blank PW or physiological phosphate-buffered saline and using this as sample instead of plasma. The concentration of the drug in the ultrafiltrate and plasma can be quantified using a LC-MS/MS. If radiolabeled drug is used, LSC can be used. The fraction of drug unbound can be calculated by using Equation 12.5 (employs correction factor for NSB, that is, ratio between drug concentration in the original PW (C_{pw}) and the concentration of the drug in PW ($C_{pw,f}$) after ultrafiltration).

$$f_u = \frac{C_f (C_{pw} / C_{pw,f})}{C_p} \quad (12.5)$$

where C_f is the concentration of drug measured in the ultrafiltrate after centrifugation of the matrix containing the drug and C_p is the concentration of the drug in the matrix before centrifugation.

The percentage of drug bound or unbound can be calculated by using Equations 12.3 and 12.4 described earlier.

To reduce NSB of drugs, pretreatment of the filter membrane with 5% Tween 80 or benzalkonium chloride has been suggested [19]. Equilibrium dialysis is considered to be more suitable for protein binding estimations if the NSB of the drug to the ultrafiltration apparatus is greater than 5%. It has also been suggested that if NSB exceeds 5%, correction for NSB for estimating the protein binding of drugs should not be used, as the presence of plasma may alter its extent.

Ultrafiltration can be performed in a single ultrafilter unit or in a 96-well plate high throughput ultrafiltration system: Ultrafiltration unit (Millipore).

Some advantages and disadvantages of ultrafiltration method are listed in the following.

Advantages

- Fast, simple, and efficient technique;
- Lack of sample dilution and volume shifts;
- No requirement of nonphysiological buffer;
- Compatible to high throughput with robotic systems.

Disadvantages

- NSB of drug to plastic tube or ultrafiltration membrane;
- Constriction of membrane pores during ultrafiltration;
- Leakage of bound drug through the membrane;
- Donnan ion effect;
- Volume of ultrafiltrate may not be sufficient for assay;
- Deviation of drug–protein binding equilibrium because of the change in protein concentration due to loss of plasma water; especially in case of high protein-bound drugs.

Figure 12.5 Ultracentrifugation method for estimating protein binding of drugs. The figure indicates the sedimentation of drug bound to protein (open circle) from the free drug (closed circle) under the influence of an extremely high centrifugal force ($150,000 \times g$) and a positive air pressure of up to 30 psi. Sampling of supernatant yields the free drug concentration.

12.2.3 Ultracentrifugation

Ultracentrifugation is based on the separation of free and protein-bound drug by application of a high centrifugal force without a membrane. The method is based on differential sedimentation of plasma constituents depending on their molecular mass. The experimental method is depicted in Fig. 12.5.

Briefly, drug is spiked in plasma and aliquots are transferred to centrifuge tubes for centrifugation at $150,000 \times g$ at an air pressure of 30 psi. The remaining plasma is maintained during the time of centrifugation. The centrifugation time is predetermined by stopping the centrifuge at different time intervals and measuring the drug concentration in the top layer. The time at which the concentration is constant is chosen for the centrifugation of the study samples. At the end of the centrifugation period, the plasma separates into distinct layers: the sedimented plasma protein layer, the supernatant PW layer, and a thin white lipoprotein layer at the surface. The drug concentrations are estimated in the supernatant PW layer ($C_{\text{supernatant}}$) and the stored spiked plasma (C_{initial}) by LC-MS/MS analysis. The fraction of drug unbound can be calculated by using Equation 12.6. The percentage of drug bound or unbound can be calculated by using Equations 12.3 and 12.4 described earlier.

$$f_u = \frac{C_{\text{supernatant}}}{C_{\text{initial}}} \quad (12.6)$$

Depending on the centrifuge available, different centrifugation times have been used. Also a microscale ultracentrifugation was evaluated by Nakai *et al.* [20], which utilized only 200 μL of plasma sample with a bench top ultracentrifuge ($436,000 \times g$, 140 min). They showed a very good correlation in the protein binding estimated for 10 compounds with this method and that determined by equilibrium dialysis or ultrafiltration. Ultracentrifugation is an alternative method to equilibrium dialysis and ultrafiltration and can be used for compounds having high NSB, as it eliminates problems associated with free membrane effects. Also, it is the best method for highly hydrophobic compounds for which other methods prove inadequate. Some advantages and disadvantages of ultracentrifugation method are listed in the following.

Advantages

- Fewer NSB issues;
- No dilution of sample.

Disadvantages

- Expensive instrumentation (high speed ultracentrifuge);
- Time consuming (up to 12–24 h centrifugation time);
- Low throughput as limited samples can be centrifuged simultaneously;
- No automation possible;
- Larger volume of sample required;
- Self-sedimentation of large-molecular-weight compounds;
- Interferences due to thermal back diffusion and floating lipoprotein in the supernatant.

12.2.4 High Performance Affinity Chromatography

High performance affinity chromatography (HPAC) for estimation of protein binding of drugs is based on the use of a liquid chromatographic technique that uses a protein as the stationary phase for the analysis of sample containing drug. The retention of the drug is based on its reversible interaction with the protein (affinity ligand). The earliest work using HSA columns was carried out by Domenici *et al.* [21]. Later, different strategies for the development of columns immobilized with HSA have been reported. The epoxy method used the epoxy groups of a copolymer (glycidyl methacrylate and ethylene dimethacrylate) for direct immobilization of HSA through its amine residues. In other approaches, the epoxy groups were converted to diols for later use in the carbonyldiimidazole, disuccinimidyl carbonate, and Schiff base methods [22]. Stable and selective chiral stationary phases were also prepared by covalent binding of HSA to silica particles via reactive polymers. Stationary phases obtained by immobilization of HSA on (C8) and (C18) reverse phases and on poly(1-vinylimidazole)-coated silica have also been reported [23]. In addition to HSA, other columns using immobilized proteins such as AAG and lipoproteins of different species are now available.

HPAC can be used to study protein binding of drugs using zonal elution and frontal analysis techniques. In both these methods, the protein of interest is used as an immobilized ligand and an injection or application of analyte is made onto the affinity column in the presence of only buffer or buffer plus a mobile phase modifier/competing agent. By examining the elution time or volume of the analyte after it has passed through the column, it is possible to obtain information on the extent of drug–protein binding, the equilibrium constants for these processes, the ability of the drug to compete with other compounds, the effects of temperature or solvent composition on these reactions, and the structure and location of the drug binding sites on the immobilized protein [24].

Some advantages and disadvantages of HPAC method are listed in the following.

Advantages

- Easy setup;
- Low cost;
- Low sample consumption.

Disadvantages

- Only binding to one protein at a time is possible that may lead to underestimation of protein binding of drug;
- For UV-inactive compounds, LC-MS/MS is needed.

12.2.5 Microdialysis

Microdialysis is a technique for *in vivo* sampling of drugs that has been used to estimate the concentrations of unbound drug present in the extracellular fluids in various tissues or organs or in the blood. The data obtained from microdialysis sampling is continuous unlike that obtained from blood sampling at specific time points, and thus, it is best represented on a time axis at the midpoint of the sampling interval [25]. A schematic describing the functioning of a microdialysis probe is shown in Fig. 12.6.

The basic setup for a microdialysis experiment consists of a microdialysis probe, a perfusion pump, and an analytical method with the required sensitivity to quantify small concentrations of substances in small volumes of sample. Briefly, a microdialysis probe, consisting of a capillary (typical outer diameter of 500 μm) with a dialysis membrane covering its tip, is implanted into a blood vessel, tissue, or organ. The probe is then perfused with a physiological buffer such as Ringer's solution at a constant flow rate

Figure 12.6 Microdialysis probe design and functioning. The figure indicates the movement of free drug from the tissue/blood vessel through the tip of the microdialysis probe that has semipermeable membrane. Using this method, after drug administration, the change in concentration of free drug can be monitored continuously over time akin to blood sampling during traditional pharmacokinetic studies.

(usually $<2\ \mu\text{L}/\text{min}$). Owing to the semipermeable membrane of microdialysis with a typical MWCO of 20 kDa, only small molecules diffuse along the concentration gradient toward the probe lumen into the perfusate. The concentration of the drug in the perfusate is analyzed by LC-MS/MS and represents the unbound drug concentration.

When using microdialysis, it is important to assess the recovery of drug. Microdialysis is not performed under equilibrium conditions because the perfusate is constantly being pumped through the probe; thus, the concentration of the drug in the perfusate is always lower than that of the extracellular fluid surrounding the dialysis probe. The ratio between these concentrations is defined as relative recovery of the analyte. The relative recovery decreases as the flow of the perfusate increases. To improve recovery of drugs, bovine serum albumin, glycerol [26], or β -cyclodextrin [27] have been added in the perfusate by some researchers.

Microdialysis allows continuous sampling from awake, freely moving animals in small numbers. Moreover, multiple site sampling can provide detailed PK information and drug transport equilibration across membranes such as blood-to-brain distributions. The microdialysis technique is devoid of any loss of biological fluid, thus enables use of the same animals as their own control in a cross-over design.

Some advantages and disadvantages of microdialysis method are listed in the following.

Advantages

- Can be used to estimate unbound drug concentrations (and kinetics) in blood or tissue in awake animals thus maintaining physiological conditions;
- Very clean dialysate requiring no sample clean-up;
- Unbound drug in the dialysate is chemically stable as the dialysate is free of any plasma or tissue components.

Disadvantages

- Low recovery of hydrophobic and highly protein-bound drugs;
- *In vitro* recovery may not translate to *in vivo* recovery due to interaction of plasma or tissue components with membrane material;
- Requirement of sensitive analytical methods that can work with low sample volumes;
- Tissue damage by microdialysis probe implantation.

12.2.6 Other Methods

Many other nonseparative methods have been used to assess protein binding of drugs. These include fluorescence measurement, surface plasmon resonance, capillary electrophoresis (CE), X-ray crystallography, absorption spectroscopy, and nuclear magnetic resonance spectroscopy.

The fluorescence measurement technique [28] uses the detection of intrinsic fluorescence of tryptophan (Trp) residues of HSA and AAG, which are the primary plasma proteins. In tryptophan fluorescence quenching (TFQ), the Trp is excited at 285 nm and the emission fluorescence is monitored as the drug is titrated into the system. The fluorescence of the intrinsic Trp in HSA is quenched by the drugs that

interact closely to the Trp. The binding constant is measured by fitting the drug concentration versus fluorescence profile. TFQ is a domain-specific binding assay that is susceptible to interference from fluorescent compounds. It cannot measure the binding constants for compounds that bind at sites distant from the Trp such that quenching is not detected. The dissociation constant K_D of analyte can then be calculated. This method can be used as a 96-well assay and is high throughput compatible.

Another high throughput method uses surface plasmon resonance biosensors [29], such as Biacore®, to study drug–plasma protein binding. In this method, one interacting partner (“ligand”) is attached to the surface of a chip and the sample containing the second interaction partner (“analyte”) is passed over the surface of the chip. Binding of molecules to the sensor surface generates changes in the resonance angle in real time, which is proportional to the bound mass. Drugs can be classified as low, medium, or high binding, and this process can be applied to large numbers and classes of compounds. When additional rigor is desired and sufficient compound is available, definitive K_D constants can be determined. The limitations of Biacore® are nonaqueous solvent effects and lack of ruggedness.

Drug–protein binding can also be studied using CE. Advantages of CE methods over chromatographic methods include its resolving power and small amounts of proteins and drugs required. The major limitation of the CE methods is their low sensitivity. In the electrophoretic techniques, the separation of the free drug, the free protein, and the drug–protein complex is based on their differences in electrophoretic mobility due to the net charge and size differences. It is simple, robust, and easy to implement; can deal with multiple equilibria; and requires less reagents than all the other methods [30].

12.3 SUMMARY

The phenomenon of plasma and tissue binding is the important determinant of the overall properties of the drug that are of importance in evaluating the PK and PD of drugs and the design of the dosage regimen. There are several methods for the estimation of plasma protein binding, and one must carefully choose the method that is commensurate with the level of information regarding plasma protein binding that is desired based on the developmental stage of the NCE or drug.

In previous chapters, the expression and function of metabolic enzymes and drug transporters have been overviewed as important factors dominating ADME (the absorption, disposition, metabolism, and excretion) of drugs. As common features, each metabolic enzyme and transporter consists of a wide variety of isoforms, and the substrate specificity of each isoform is very broad, thereby providing an evolutionary ability to protect the body against numerous kinds of xenobiotics. Thus, a single compound can often be recognized by multiple metabolic enzymes and transporters as a substrate because it partly overlaps with different isoforms of enzymes and transporters. These molecules are appropriately located at several tissues in the body and increase efficiency in the detoxification of xenobiotics. For example, in the liver, efficient detoxification can be achieved by the sequential processing of compounds, such as in the cellular uptake from the blood circulation to hepatocytes via influx transporters, phase I and II metabolism, and biliary excretion via efflux transporters.

In this chapter, we present an overview of how combinations of enzymes and transporters work concertedly as a detoxification “system”. Moreover, when evaluating the efficiency of detoxification quantitatively, because these molecules have different roles and do not function in parallel in this system, clearance of xenobiotics in each tissue cannot be expressed simply as the sum or product of an intrinsic clearance of each isoform of metabolic enzymes and transporters. Therefore, we will also discuss theoretical considerations and experimental methods to evaluate the influence of the function of each molecule on the overall efficiency of a detoxification system from the viewpoint of pharmacokinetics.

13.1 VECTORIAL TRANSPORT OF XENOBIOTICS IN TISSUES

Most xenobiotics are transferred to the liver and kidney, extensively metabolized in the liver, and excreted into bile and urine as an unchanged form or as metabolites for detoxification. In those processes, compounds must pass through both the basal and the apical membranes of hepatocytes and kidney tubular epithelial cells to reach the bile and urine compartments: this is called *transcellular transport* [1]. Such transcellular transport of drugs can also be seen in various other tissues such as intestinal epithelial cells as a site of drug absorption and the brain capillary endothelial cells as a major component of the blood–brain barrier. In general, because gap junctions seal the intercellular space tightly and transport between cells is very limited, transcellular transport is a major contributor to drug movement across cells, although paracellular transport sometimes plays a partial role in the intestinal absorption of small hydrophilic compounds according to Renkin's equation [2]. To enhance the efficiency of detoxification, basal-to-apical directional transcellular transport ("vectorial transport") of compounds is achieved with the aid of uptake and efflux transporters. For example, in the liver and kidney, several uptake transporters are expressed on the basal membrane facing the blood circulation and efflux transporters are expressed on the apical membrane facing the bile or urine. This allows the compounds to be concentrated into the bile and urine from the systemic blood.

For lipophilic compounds, because they can penetrate the plasma membrane easily, vectorial transport can be achieved only by the expression of efflux transporters. However, hydrophilic compounds cannot access efflux transporters because of their poor membrane permeability, and thus, both uptake and efflux transporters are required for their transcellular transport. For example, the bile-to-plasma concentration ratio of pravastatin, a nonmetabolized type of HMG-CoA reductase inhibitor (statin), is calculated to be about 960 in rats [3]. In fact, pravastatin is well known to be a substrate of the hepatic uptake transporter, OATP (organic anion transporting polypeptide) 1B1 and the efflux transporter, MRP2 (multidrug resistance-associated protein 2), which contribute to its concentrative transport in the bile and subsequent efficient excretion [4]. Such vectorial transport can be utilized in other tissues such as the small intestine and blood–brain barrier to strictly regulate the flux of necessary and unnecessary compounds in the body [1].

As shown in Fig. 13.1, vectorial transport is mediated by two different types of transporters, the ABC (ATP-binding cassette) family and the SLC (solute carrier) family transporters. The ABC family transporters are driven by the hydrolysis of intracellular ATP and mediate efflux transport from the inside to the outside of cells. Conversely, the SLC family transporters can transport compounds bidirectionally, depending on the concentration gradient of the driving force. For example, hepatic OATP family transporters generally take up compounds from the blood to hepatocytes, although the endogenous driving force has not been fully clarified [5], whereas the apically localized renal MATE (multidrug and toxin extrusion) transporters are considered to be involved in the efflux of cationic drugs into the urine driven by an exchange of H^+ ions [6]. The combinations of transporters for the transcellular transport of compounds differ depending on the physicochemical properties of compounds. In the case of organic anions, because the intracellular compartment is negatively charged and it is difficult for anions to gain access to the inside of cells from the outside via facilitated diffusion, active transport machineries must be involved in their uptake. Their efflux involves

Figure 13.1 Role of SLC and ABC transporters in the transcellular transport of compounds in various tissues. Key: ABC, ATP-binding cassette transporter; SLC, solute carrier-type transporter. *Source*: This figure is cited from Ref. 1.

both facilitated diffusion-type transporters, such as OST α/β (organic solute transporter α/β), and ABC transporters, such as MDR1 (multidrug resistance 1) and MRP2. On the other hand, in the case of cationic compounds, their uptake is mediated by facilitated diffusion-type transporters such as OCTs (organic cation transporters), whereas active transport mechanisms such as MATEs are mainly involved in their efflux.

Table 13.1 shows some examples of vectorial transport of endogenous and exogenous compounds mediated by the cooperation of uptake and efflux transporters [7]. Bile acids are distributed predominantly in the gastrointestinal tract and liver. This is achieved by the efficient enterohepatic circulation, consisting of both a transcellular transport system in the liver mediated by NTCP (Na⁺-taurocholate cotransporting polypeptide) and BSEP (bile salt export pump), and in the intestine mediated by ASBT (apical Na⁺-dependent bile acid transporter) and OST α/β [8]. This type of enterohepatic circulation also benefits the pharmacological and toxicological effects of statins. For example, the transcellular transport of pravastatin in the liver is dominated by OATPs (uptake) and MRP2 (efflux), and its reuptake in the small intestine is thought to be mediated by the OATP family transporters [4]. The enterohepatic circulation contributes to the long-term accumulation of statins in the liver and to the subsequent sustained exposure to intrahepatic HMG-CoA reductase, a pharmacological target of statins. It also contributes to their low level in the blood circulation and a decreased risk of myopathy, which is one of the major side effects of statins.

TABLE 13.1 Transporter-Mediated Vectorial Transport of Compounds in the Tissues

Organ	Substrates	Basal Transporter	Direction	Apical Transporter
Liver	Organic anions	OATP1B1/OATP1B3/ OATP2B1	→	MDR1/MRP2/BCRP
Kidney/small intestine	Bile acids	NTCP	→	BSEP
	Dipeptide/peptide mimetics	(not identified)	←	PEPT1/PEPT2
Kidney	Organic anions	OAT1/OAT3	→	RST/NPT1/NPT4/ MRP4/MRP2/ OAT4/BCRP/ MDR1
	Organic cations	OCT2	→	OCTN1/OCTN2/ MATE1/MATE2/ MDR1
	Glucose	GLUT1/GLUT2	←	SGLT
	Nucleobase	ENT	←	CNT
	Carnitine	(not identified)	←	OCTN2
	Urate	OAT1/OAT3	→	NPT4
	Urate	GLUT9	←	RST
	Bile acids	OSTa/b	←	ASBT
	Folate/folate analogs	(not identified)	←	PCFT/RFC
Intestine				

Direction: →, basal-to-apical transport, ←, apical-to-basal transport.

Please note that combinations of transporters involved in the vectorial transport largely depends on the compounds.

This table contains some transporters whose *in vivo* role in the vectorial transport of compounds has not been fully clarified.

Source: This table is cited from Ref. 7 with some modifications.

Figure 13.2 Major systems of drug detoxification in hepatocytes.

13.1.1 Vectorial Transport Machineries in the Liver

Figure 13.2 illustrates the major transporters expressed in hepatocytes. As mentioned above, transcellular transport of bile acids is mainly dominated by NTCP and BSEP. Clinically important anionic drugs including statins and angiotensin II receptor antagonists (sartans) are taken up into hepatocytes mainly via OATP1B1 and OATP1B3. Because the substrate specificities of OATP1B1 and OATP1B3 are very broad and are similar to each other, one compound is often recognized by both transporters. Previous reports suggested that the relative contribution of OATP1B1 and OATP1B3 to the hepatic uptake differs between substrates, although these anionic compounds accumulate preferentially in the liver [9]. For example, the hepatic uptake of valsartan is mediated by both OATP1B1 and OATP1B3 to the same extent [10], but that of telmisartan is exclusively dominated by OATP1B3 [11] even in the same category of drugs (sartans). These differences in the contribution of each transporter affect the extent of change in the overall intrinsic clearance of these compounds when the function of a single transporter is altered by genetic polymorphisms or drug interactions. OAT2 is also expressed on the basal membrane in the hepatocytes and accepts various structurally unrelated compounds such as bumetanide, zidovudine, 5-fluorouracil (5-FU), paclitaxel, and prostaglandin E₂ [12]. However, the relative contribution of OAT2 to the overall *in vivo* hepatic uptake of substrates is not fully understood.

OCT1 mediates hydrophilic organic cations with a relatively low molecular weight such as metformin and TEA (tetraethylammonium) [13]. Various kinds of ABC transporters expressed on the apical membrane are involved in biliary excretion. Generally, MDR1 preferentially transports various kinds of bulky hydrophobic and cationic compounds, MRP2 mainly transports anionic compounds including several conjugated metabolites such as glucuronide and glutathione conjugates, and BCRP can also

transport a wide variety of compounds, especially sulfated conjugates [14]. However, this rule is not always applicable to some compounds. MDR1 can sometimes transport anionic and zwitterionic drugs such as E₂17 β G (estradiol-17 β -glucuronide) and fexofenadine, and BCRP can transport cationic (cimetidine), zwitterionic (mitoxantrone), and neutral (topotecan) compounds as well as anionic compounds. Recent reports have shown that MATE1 is also expressed on the apical membrane of hepatocytes and is involved in the biliary excretion of cationic drugs such as metformin, since coadministration of pyrimethamine, a potent and specific inhibitor for MATEs, or gene knockout of MATE1 expression increased the hepatic distribution of metformin [15,16].

The vectorial transport of compounds mediated by uptake and efflux transporters in the liver was mimicked experimentally by the use of double-transfected cells. Originally, Cui *et al.* and Sasaki *et al.* constructed OATP1B3/MRP2 and OATP1B1/MRP2 double-transfected MDCKII cells, respectively, and they demonstrated the basal-to-apical vectorial transport of several organic anions in the monolayer of these cell systems on a transwell membrane insert [17,18]. Sasaki *et al.* have demonstrated that *in vivo* biliary clearance was predicted quantitatively from the vectorial transcellular transport of several compounds in rat Oatp1b2/Mrp2 double-transfected cells [19]. Subsequently, a set of double-transfected cells expressing OATP1B1/OATP1B3 (uptake) and MDR1/MRP2/BCRP (efflux) were constructed for rapid screening of the machineries involved in the vectorial transport of compounds [20]. For example, basal-to-apical vectorial transport of E₂17 β G and pravastatin was largely enhanced in OATP1B1/MRP2 double-transfected cells compared with OATP1B1/MDR1 and OATP1B1/BCRP cells (Fig. 13.3), suggesting that the combination of OATP1B1-mediated uptake and MRP2-mediated efflux controls the efficient biliary excretion of these compounds [20]. This is supported by the drastic decrease in the biliary excretion of these compounds in the Mrp2-hereditary-deficient rat strain, EHBR (Eisai hyperbilirubinemic rat) [21,22]. Kopplow *et al.* have also constructed a quadruple-transfected cell line expressing OATP1B1, OATP1B3, OATP2B1, and MRP2 to better understand the substrate selectivity of MRP2 [23], because most of the substrates for that OATP family transporters are also substrates for MRP2, although they do not share homology with each other. For organic cations, double-transfected MDCKII cells expressing OCT1 and MDR1 were constructed and vectorial transport of berberine, a cationic plant alkaloid, was confirmed in this system [24]. Sato *et al.* have constructed OCT1/MATE1 double-transfected MDCK cells, and several cations such as TEA, metformin, and cimetidine could be transported vectorially from the basal to the apical sides of cell monolayers [25,26].

13.1.2 Vectorial Transport Machineries in the Kidney

Figure 13.4 illustrates the major transporters expressed in the proximal tubular epithelial kidney cells. OAT1 and 3 are thought to be involved mainly in the uptake of organic anions [12,27]. OAT1 accepts several kinds of small and hydrophilic organic anions such as PAH (*p*-aminohippurate) and nucleotide analog reverse-transcriptase inhibitors (adefovir, tenofovir, and cidofovir). On the other hand, OAT3 accepts a wide variety of bulky hydrophobic/amphipathic organic anions and its substrate specificity generally overlaps that of the OATP family transporters, although the protein sequences of these transporters are not similar. OAT3 can also transport cationic drugs such as histamine

Figure 13.3 Transcellular transport of estradiol-17β-glucuronide (E₂ 17βG) and pravastatin in double-transfected cells expressing OATP1B1 and MDR1, MRP2, or BCRP. *Source:* This figure is cited from Ref. 20.

Figure 13.4 Major drug transporters for the transcellular transport of compounds in the kidney.

H₂ blockers (cimetidine, famotidine, ranitidine). As for the luminal efflux of intracellular anionic compounds to urine, considering the inside negative electrical potential, facilitated diffusion as well as active transport can be involved in the efflux of anionic compounds in the kidney. On the apical membrane, both ABC transporters such as MDR1, MRP2, MRP4, and BCRP and facilitative diffusion-type transporters such as RST [renal-specific transporter (in rodents); URAT1 (urate transporter) (in humans)], NPT (Na⁺-dependent phosphate transport protein) 1, and NPT4 are known to be expressed [27]. Previous *in vitro* experiments using BBMVs (brush border membrane vesicles) suggested that at least two different transport systems, electroneutral exchange of organic anions and voltage-dependent facilitated diffusion, are involved in the luminal efflux of anions. However, there are few lines of evidence showing the importance of these transporters in the renal efflux of anions *in vivo*. The use of transporter knockout mice revealed that Bcrp is responsible for the luminal efflux of methotrexate, E3040 sulfate, and edaravone sulfate [28,29] and Mrp4 is involved in the luminal efflux of diuretics (hydrochlorothiazide and furosemide), antiviral drugs (adefovir and tenofovir), cephalosporins (ceftizoxime and cefazolin), and edaravone glucuronide [27]. In *in vitro* experiments using OAT3/RST double-transfected cells, basal to apical vectorial transport of benzylpenicillin, urate, and 2,4-dichlorophenoxyacetate was observed clearly, suggesting the role of these transporters in the urinary excretion of these compounds, although the significance of RST (URAT1) *in vivo* has not been demonstrated directly [30]. Urate is both secreted and reabsorbed in the kidney, and 90% of urate excreted via glomerular filtration is ultimately returned to the body. Recent clinical genetic studies and *in vitro* experiments suggested that the renal secretion of urate is thought to be dominated by uptake via OAT1/OAT3 and efflux via NPT4, while its reabsorption is mediated by uptake via URAT1 and efflux via GLUT (glucose transporter) 9 [31]. This hypothesis is partly supported by previous *in vivo* phenotypic observations of transporter knockout mice, although the metabolic fate of urate is totally different in rodents and humans. *In vitro* studies showed that NPT1 can transport some other organic anions such as PAH, benzylpenicillin, faropenem, and E₂17βG and that NPT4 can transport PAH, estrone-3-sulfate, E₂17βG, bumetanide, and ochratoxin A [32,33]. Thus, these NPT transporters might also contribute to the secretory vectorial transport of anionic compounds in cooperation with OATs.

Conversely, the renal uptake of hydrophilic and small organic cations is mainly mediated by OCT2 [34]. OCTN1, OCTN2, and MATEs, as well as MDR1 are expressed on the apical side of renal tubular epithelial cells. However, the transporter responsible for the renal efflux of cationic compounds *in vivo* is still under investigation, as it presumably acts in cooperation with OCT2. Ohashi *et al.* demonstrated that the renal secretion clearance of TEA was reduced to half in OCTN2-deficient *jvs* (juvenile visceral steatosis) mice, suggesting the importance of OCTN2 in the efflux of TEA in the kidney [35]. MATE family transporters (MATE1, MATE2, and MATE2-K) accept various kinds of organic cations such as metformin, fexofenadine, antiviral drugs (acyclovir, ganciclovir), anticancer drugs (oxaliplatin, cisplatin, and topotecan), and antibiotics (cephalexin, cephadrine, and levofloxacin) [36,37]. Recent studies *in vivo* indicated that the kidney-to-plasma concentration ratios of TEA and metformin were increased by the coadministration of pyrimethamine, a potent selective MATE inhibitor, in mice. Moreover, the renal clearance of metformin, cephalexin, and cisplatin was decreased significantly in MATE1 gene knockout mice [15,16]. Kusuvara *et al.* also demonstrated that the renal clearance of metformin was decreased by 35%

when it was coadministered with pyrimethamine in healthy human subjects [38]. Thus, MATEs as well as OCT2 are considered to be responsible for the efficient secretory transport of metformin in the human kidney. *In vitro* experiments using OCT2/MATE1 double-transfected MDCK cells showed that the basal-to-apical transcellular transport of several cations such as TEA, metformin, cimetidine, procainamide, and quinidine was significantly higher than that in the opposite direction [25,26]. Thus, renal secretion of these compounds is thought to be dominated by uptake via OCT2 and efflux via MATE1.

As for reabsorption process in the kidney, although it is well known that several nutrients (e.g., amino acids, sugars, and vitamins) extensively undergo renal reabsorption from the lumen side, the combinations of uptake and efflux transporters dominating apical-to-basal vectorial transport of xenobiotics have not yet been fully clarified. Knockout of PEPT2, a peptide transporter, increased the renal clearance of cephadoxil and carnosine, suggesting that PEPT2 is involved in their renal reabsorption [39]. However, the transporters responsible for the basal efflux have not been determined. Oatp1a1 is also expressed on the apical renal membrane in male rats but almost not in female rats [40,41]. Previous studies demonstrated that the renal clearance of E₂17 β G, dibromosulfophthalein, and zenarestat was significantly higher in male than in female rats, suggesting a role for Oatp1a1 in the uptake of compounds at the apical side of the kidney [40,41]. In contrast, there is no information about the corresponding OATP transporter gene expressed on the apical membrane of human kidneys or about the gender differences in the renal clearance of compounds in humans.

13.2 KINETIC CONSIDERATION OF KEY FACTORS DETERMINING THE ORGAN CLEARANCE

Excretion systems in the liver and kidney consist of multiple uptake and efflux transporters and metabolic enzymes. Because these molecules do not work sequentially one by one or in parallel for the detoxification of xenobiotics, organ clearance, an indicator for the performance of the detoxification system, cannot be simply defined by the sum or product of the intrinsic activity (transport/metabolism) of each molecule. In each process such as uptake, efflux, and metabolism, multiple molecules are involved simultaneously, thanks to their broad and overlapping substrate specificities. Thus, we must consider the relative contribution of each molecule to the overall activity of each step. Organ intrinsic clearance is dominated by uptake, efflux, backflux to the blood circulation, and metabolism and can be described theoretically by using the intrinsic activity of each step. Then, organ clearance can be estimated from multiple factors such as the overall intrinsic clearance, blood flow, and protein unbound fraction in a model-dependent manner. In this section, we describe how the intrinsic activity of each molecule affects the performance of detoxification system in the *in vivo* situation quantitatively, from the viewpoint of pharmacokinetic theory. Such a consideration is essential to estimate the extent of change in the total clearance and exposure of drugs in the body when the expression and function of each molecule are altered by several factors such as genetic polymorphisms, interacting drugs, and pathophysiological conditions.

13.2.1 Contribution of Each Isoform to the Overall Metabolism/Transport

In each step of detoxification such as uptake, efflux, backflux, and metabolism, multiple transporters or metabolic enzymes often work in parallel. For metabolism, metabolic intrinsic clearance (CL_{met}) can be simply described as the sum of the intrinsic clearance of each metabolic enzyme ($CL_{\text{enzyme},i}$) as

$$CL_{\text{met}} = CL_{\text{enzyme},1} + CL_{\text{enzyme},2} + \cdots + CL_{\text{enzyme},i} \quad (13.1)$$

On the other hand, for the membrane transport of lipophilic compounds, we must also think about the contribution of passive permeation as well as active transport. Thus, intrinsic membrane transport clearance ($PS_{\text{transport}}$) is the sum of the intrinsic clearance of passive transport (CL_{passive}) and active transport mediated by each transporter ($CL_{\text{TP},i}$).

$$PS_{\text{transport}} = CL_{\text{passive}} + CL_{\text{TP},1} + CL_{\text{TP},2} + \cdots + CL_{\text{TP},i} \quad (13.2)$$

The impact of the relative contribution of each molecule on the overall intrinsic clearance can be tested virtually in a model case. Assuming that drug A is eliminated only by the hepatic metabolism and that its pharmacokinetics follow the well-stirred model, when drug A is orally administered, the area under the plasma concentration–time curve (AUC) can be described by the following equation.

$$\begin{aligned} AUC_{\text{oral}} &= \frac{F_a F_g \cdot F_h \cdot \text{Dose}}{CL_h} = \frac{F_a F_g \frac{Q_h}{Q_h + f_B CL_{\text{int},h}} \text{Dose}}{\frac{Q_h f_B CL_{\text{int},h}}{Q_h + f_B CL_{\text{int},h}}} = \frac{F_a F_g \cdot \text{Dose}}{f_B CL_{\text{int},h}} \\ &= \frac{F_a F_g \cdot \text{Dose}}{f_B (CL_{\text{enzyme},1} + CL_{\text{enzyme},2} + \cdots + CL_{\text{enzyme},i})} \end{aligned} \quad (13.3)$$

Here, $F_a F_g$ is the intestinal availability, F_h the hepatic availability, CL_h the hepatic clearance, Q_h the hepatic blood flow rate, f_B the protein unbound fraction in blood, and $CL_{\text{int},h}$ the hepatic intrinsic clearance.

Under this situation, if the function of enzyme 1 is decreased to $1/R$, the fold increase in the AUC_{oral} value largely depends on the relative contribution of intrinsic clearance mediated by enzyme 1 to the overall metabolic clearance ($f_{m,1}$).

$$\begin{aligned} AUC_{\text{oral ratio}} &= \frac{f_B (CL_{\text{enzyme},1} + CL_{\text{enzyme},2} + \cdots + CL_{\text{enzyme},i})}{f_B \left(\frac{CL_{\text{enzyme},1}}{R} + CL_{\text{enzyme},2} + \cdots + CL_{\text{enzyme},i} \right)} \\ &= \frac{f_{m,1} \cdot CL_{\text{int},h} + (1 - f_{m,1}) CL_{\text{int},h}}{f_{m,1} \cdot \frac{CL_{\text{int},h}}{R} + (1 - f_{m,1}) CL_{\text{int},h}} = \frac{1}{f_{m,1} \cdot \frac{1}{R} + (1 - f_{m,1})} \end{aligned} \quad (13.4)$$

Following Equation 13.4, the fold increase in the AUC_{oral} is plotted against the inhibition potency of enzyme 1 (R) in Fig. 13.5. If enzyme 1 is inhibited potently, the AUC_{oral} ratio shows large difference even when the relative contribution ($f_{m,1}$) changes slightly. Thus, the quantitative estimation of the contribution of each molecule to the overall intrinsic clearance is important if we correctly predict the AUC change caused by the functional change of a single molecule.

Figure 13.5 Importance of the contribution of a specific enzyme to the overall metabolism in the increase of the AUC_{oral} value. Theoretical calculation of the AUC_{oral} ratio ($AUC_{oral} (+inhibitor)/AUC_{oral} (control)$) is performed when enzyme 1 contributes $f_{m,1}$ values of 1.0, 0.99, 0.9, 0.7, and 0.5 of the total metabolic activity and the metabolic activity of enzyme 1 is specifically decreased to $1/R$.

Niemi *et al.* [42] showed that the AUC of repaglinide, a substrate of CYP2C8 and CYP3A4, was increased by 8.1-fold in coadministration with gemfibrozil, a potent inhibitor of CYP2C8, and increased by 1.4-fold in coadministration with itraconazole, a potent inhibitor of CYP3A4. On the other hand, in coadministration with both gemfibrozil and itraconazole, the AUC of repaglinide increased greatly by 19.4-fold [42]. This seems to be a synergistic inhibitory effect of gemfibrozil and itraconazole. However, this kind of drug interaction can be explained only by conventional pharmacokinetic theory, considering the contribution of each molecule. We assume that drug B is eliminated by three different metabolic pathways mediated by enzymes X, Y, and Z, and that the relative contributions (f_m) of enzymes X, Y, and Z to the overall metabolism of drug B are 0.5, 0.4, and 0.1, respectively. In this situation, when drug B is coadministered with a potent inhibitor of enzyme X, according to Equation 13.4, the AUC of drug B is expected to be increased by 2-fold, while its AUC is increased by 1.7-fold when coadministered with a potent inhibitor of enzyme Y. On the other hand, when both enzymes X and Y are completely inhibited by coadministration of both inhibitors, the AUC of drug B is increased drastically up to 10-fold because the metabolic intrinsic clearance becomes one-tenth of that in a control situation. Therefore, it must be noted that a combination of inhibitor drugs for different metabolic pathways can sometimes increase the exposure of the victim drug significantly, although the complete inhibition of a single metabolic pathway does not affect the drug concentration so much.

A similar story is also discussed in a recent paper by Kusuvara and Sugiyama [43] concerning the apparent synergistic effect of the P-gp and BCRP on the brain distribution of substrates. There is some evidence demonstrating that the double knockout of P-gp and Bcrp expression in mice produced remarkable increases in the concentration of some drugs in the brain, whereas single knockouts of P-gp or Bcrp showed only

A hypothetical common substrate drug with following kinetic parameters:
 $PS_{2,u} = 0.5$, $PS_{BCRP} = 2$, $PS_{P-gp} = 5$

Figure 13.6 Theoretical consideration of the apparent synergistic effects of P-gp and BCRP knockout on the brain distribution of substrates. The simple model for the transcellular transport of compounds at the blood–brain barrier was constructed and $K_{p,brain}$ was estimated when each parameter was set at the designated values shown in this figure. Then, $K_{p,brain}$ values were compared between wild type, P-gp knockout, BCRP knockout, and P-gp/BCRP double-knockout mice. *Source:* This figure is cited from Ref. 43.

limited effects [44–46]. This apparent synergism can be explained by simple pharmacokinetic theory without considering any interplay between the P-gp and Bcrp [43,47]. Following the schematic diagram of the membrane transport in brain endothelial cells, brain-to-blood concentration ratio ($K_{p,brain}$) can be described by the parameters shown in Fig. 13.6 according to the following equation.

$$K_{p,brain} = \frac{PS_{blood \rightarrow brain}}{PS_{brain \rightarrow blood}} = \frac{PS_{1,u} \frac{PS_{3,u}}{PS_{P-gp} + PS_{BCRP} + PS_{2,u} + PS_{3,u}}}{PS_{4,u} \frac{PS_{2,u}}{PS_{P-gp} + PS_{BCRP} + PS_{2,u} + PS_{3,u}}} = \frac{PS_{1,u} \cdot PS_{3,u}}{PS_{4,u} (PS_{P-gp} + PS_{BCRP} + PS_{2,u})} \quad (13.5)$$

Thus, the ratio of the $K_{p,brain}$ value in knockout mice to that in normal mice is

$$K_{p,brain} \text{ ratio(P-gp)} = \frac{\frac{PS_{1,u} \cdot PS_{3,u}}{PS_{4,u} (PS_{BCRP} + PS_{2,u})}}{\frac{PS_{1,u} \cdot PS_{3,u}}{PS_{4,u} (PS_{P-gp} + PS_{BCRP} + PS_{2,u})}} = 1 + \frac{PS_{P-gp}}{PS_{BCRP} + PS_{2,u}} \quad (13.6)$$

$$K_{p,brain} \text{ ratio(BCRP)} = \frac{\frac{PS_{1,u} \cdot PS_{3,u}}{PS_{4,u} (PS_{P-gp} + PS_{2,u})}}{\frac{PS_{1,u} \cdot PS_{3,u}}{PS_{4,u} (PS_{P-gp} + PS_{BCRP} + PS_{2,u})}} = 1 + \frac{PS_{BCRP}}{PS_{P-gp} + PS_{2,u}} \quad (13.7)$$

$$K_{p,brain} \text{ ratio(P-gp/BCRP)} = \frac{\frac{PS_{1,u} \cdot PS_{3,u}}{PS_{4,u} \cdot PS_{2,u}}}{\frac{PS_{1,u} \cdot PS_{3,u}}{PS_{4,u} (PS_{P-gp} + PS_{BCRP} + PS_{2,u})}} = 1 + \frac{PS_{P-gp} + PS_{BCRP}}{PS_{2,u}} \quad (13.8)$$

Therefore, when the absolute value of each parameter is set according to Fig. 13.6, the $K_{p, \text{brain}}$ ratios in P-gp and Bcrp single-knockout mice increase slightly by 3- and 1.4-fold, respectively, whereas that in P-gp/Bcrp double-knockout mice largely increases by 15-fold, which reproduces the apparent synergism of the *in vivo* observation [43].

Predictive methods to estimate the relative contribution of each molecule to the overall intrinsic clearance have been established and validated in the fields of both metabolic enzymes and transporters. For metabolism, Crespi and Penman [48] originally published the concept of the RAF (relative activity factor) method. In this, the metabolic clearance of a test compound and a selective substrate for each enzyme is measured in liver microsomes, and the recombinant enzyme expression system and the ratio of the clearance of each selective substrate in liver microsomes to that in the expression system are estimated for each enzyme ($R_{\text{enzyme}, i}$). Then, the contribution of enzyme 1 to the overall metabolic enzyme ($f_{m, \text{enzyme}, 1}$) can be described as follows.

$$f_{m, \text{enzyme}, 1} = \frac{R_{\text{enzyme}, 1} \cdot \text{CL}_{\text{test}, \text{enzyme}, 1}}{\sum_i R_{\text{enzyme}, i} \cdot \text{CL}_{\text{test}, \text{enzyme}, i}} \left(= \frac{R_{\text{enzyme}, 1} \cdot \text{CL}_{\text{test}, \text{enzyme}, 1}}{\text{CL}_{\text{int}, h}} \right) \quad (13.9)$$

Here, $\text{CL}_{\text{test}, \text{enzyme}, i}$ is the metabolic clearance of a test compound in a recombinant expression system for enzyme i .

Now, an *in vitro* selective substrate for each CYP isoform has been established almost completely. Another method is to use a selective inhibitor for each isoform. In the field of CYP enzymes, chemical selective inhibitor and functional neutralizing antibody for each major CYP isoform have also been established. The metabolic clearance of a test compound is measured in the absence and presence of a selective inhibitor and then the contribution of enzyme 1 to the overall metabolic enzyme ($f_{m, \text{enzyme}, 1}$) can be described as follows.

$$f_{m, \text{enzyme}, 1} = 1 - \frac{\text{CL}_{\text{test}}(+\text{inhibitor})}{\text{CL}_{\text{test}}(-\text{inhibitor})} \quad (13.10)$$

Similar methods can be used in the field of drug transporters. Kouzuki *et al.* [49,50] applied the RAF method to estimate the relative contributions of Ntcp and Oatp1a1 to the overall uptake of compounds in rat hepatocytes. E₂17βG and taurocholate were used as selective substrates for Oatp1a1 and Ntcp, respectively, although E₂17βG is no longer used as a reference compound for Oatp1a1. Hirano *et al.* [51] have established a method for estimating the relative contribution of OATP1B1 and OATP1B3 to the overall uptake of E₂17βG and pitavastatin in human hepatocytes by using estrone-3-sulfate (E-sul) and cholecystokinin octapeptide (CCK-8) as selective substrates for OATP1B1 and OATP1B3, respectively. They calculated the ratio of the uptake clearance of the reference compounds in human cryopreserved hepatocytes to that in the transporter expression systems ($R_{\text{act}, \text{transporter}}$). The uptake clearance of test compounds mediated by a specific transporter in hepatocytes can be calculated by multiplying the $R_{\text{act}, \text{transporter}}$ value by the uptake clearance of test compounds in the expression system ($\text{CL}_{\text{test}, \text{transporter}}$). If we can assume that test compounds are taken up into hepatocytes exclusively by OATP1B1 and OATP1B3 then the uptake clearance of test compounds in hepatocytes ($\text{CL}_{\text{test}, \text{hep}}$) should be described by the following equation.

$$CL_{\text{test, hep}} = R_{\text{act, OATP1B1}} \cdot CL_{\text{test, OATP1B1}} + R_{\text{act, OATP1B3}} \cdot CL_{\text{test, OATP1B3}} \quad (13.11)$$

Using this method, they demonstrated that both $E_217\beta G$ and pitavastatin were taken up into hepatocytes mainly via OATP1B1. The use of a selective inhibitor for each isoform is also available to estimate the contribution of OATP1B1 and OATP1B3 to the uptake of compounds in human hepatocytes [11]. Thus, E-sul can be used as a specific inhibitor for OATP1B1. The uptake of $E_217\beta G$ and pitavastatin in human hepatocytes was almost inhibited in the presence of an excess of E-sul, which further supports the major contribution of OATP1B1. Conversely, telmisartan uptake was observed only in OATP1B3-expressing cells but not in OATP1B1-expressing cells and the uptake of telmisartan in human hepatocytes was not inhibited by E-sul, suggesting that telmisartan is transported predominantly by OATP1B3 [11]. Figure 13.7 summarizes our findings of the contributions of OATP1B1 and OATP1B3 to the hepatic uptake of substrates. Even in the same category of drugs, the relative importance of OATP1B1 and OATP1B3 is different between valsartan (OATP1B1 = OATP1B3) and telmisartan (OATP1B3 $\gg$ OATP1B1). This kind of information is useful when considering the effect of genetic polymorphisms and drug interactions on the changes in pharmacokinetics of substrate drugs. Previous clinical pharmacogenetic studies indicated that the pharmacokinetics of some statins are clearly affected by SNPs (single nucleotide polymorphism) in OATP1B1 but not telmisartan [52,53].

A similar type of investigation was also performed by using rat and human kidney slices to estimate the contribution of OAT1 and OAT3 to the renal uptake of compounds. Hasegawa *et al.* [54,55] have established a RAF method for renal uptake by using PAH and pravastatin as selective substrates for rat Oat1 and Oat3, respectively, and demonstrated that renal uptake clearance predicted using the RAF method was similar to that observed in rat kidney slices in most cases. Using this method, the contributions of Oat1 and Oat3 to the renal uptake of several uremic toxins have been determined, and these results were further validated by observing the inhibitory effects of PAH (an OAT1-selective inhibitor), PCG, and pravastatin (an OAT3-selective inhibitor) on their uptake in rat kidney slices [56].

Figure 13.7 Relative contribution of OATP1B1 and OATP1B3 to the overall hepatic uptake of compounds estimated in human cryopreserved hepatocytes. This figure indicates which compounds are taken up in the hepatocytes, mainly mediated by OATP1B1 (left), OATP1B3 (right), or both OATP1B1 and OATP1B3 (center).

Sandwich-cultured hepatocytes have been utilized for the characterization of efflux from hepatocytes to the bile. LeCluyse *et al.* [57,58] have demonstrated that hepatocytes cultured between layers of collagen gel or Matrigel could efficiently repolarize and form what they termed a *bile pocket* between adjacent cells, which mimics the bile canalicular compartment in the liver and depletion of Ca^{2+} from the incubation medium rapidly disrupted the closed bile pocket by opening tight junctions. Thus, the amounts of compounds excreted into the bile pocket can be estimated by their differential cumulative uptake in sandwich-cultured hepatocytes preincubated with Ca^{2+} -containing and Ca^{2+} -free buffers. Recent studies succeeded in the use of siRNA for inhibiting each efflux transporter in determining its contribution to the overall efflux of compounds into the bile pocket. Tian *et al.* [59] demonstrated that knockdown of Mrp2 by siRNA in rat sandwich-cultured hepatocytes resulted in a 50% decrease in the protein expression and a 45% decrease in the biliary excretion index (BEI) of carboxydichlorofluorescein (CDF), which is reported to be excreted predominantly into the bile under the control of Mrp2 in rats. Bcrp knockdown by adenoviral vector-mediated RNAi (RNA interference) also succeeded, and the protein expression of Bcrp was drastically decreased to 5% of control at day 6 after starting the culture of rat hepatocytes, whereas the BEI value of nitrofurantoin, a selective substrate of Bcrp, was also decreased to 11% of control [60]. The BEI value of $^{99\text{m}}\text{Tc}$ -sestamibi, which is used for hepatobiliary scintigraphy, in the bile pocket was not decreased by treatment with a Bcrp siRNA-expressing adenovirus, but its efflux was totally abolished in the presence of GF120918, a typical inhibitor for both Mdr1 and Bcrp, suggesting that $^{99\text{m}}\text{Tc}$ -sestamibi can be used as a selective substrate for Mdr1 in rat hepatocytes [61].

Renal BBMVs are useful tools for characterizing efflux transport systems in the kidney [62]. However, because the responsible transporters have not been well characterized and the driving force of efflux transporters is required to be known for the transport assay using BBMVs, it is difficult to estimate the contribution of each transporter to the overall efflux of compounds in the kidney. For reabsorption, we can understand the involvement of reabsorption in the renal clearance qualitatively by observing the reduction in reabsorption by diuresis induced by mannitol [63]. However, there is no appropriate *in vitro* experimental system for the quantitative analysis of transporters involving reabsorption at present.

13.2.2 Rate-limiting Step of the Overall Intrinsic Clearance in a Tissue

In traditional pharmacokinetic theory, we normally regard the metabolic intrinsic clearance to be the same as the hepatic intrinsic clearance. Previous reports suggested that the *in vivo* hepatic clearance of various CYP substrate drugs could be well predicted from the *in vitro* metabolic intrinsic clearance estimated by using liver microsomes. However, this model cannot be applied to the transporter substrates, which are extensively excreted into bile as unchanged forms with minimal metabolism, such as some statins (pravastatin, pitavastatin, rosuvastatin) because the hepatic clearance is relatively large, while metabolic clearance is too low to be estimated. Lam *et al.* [64] suggested that the *in vivo* intrinsic clearance of digoxin could be better predicted from the *in vitro* intrinsic clearance with primary rat hepatocytes rather than that observed with liver microsomes. Frassetto *et al.* have also demonstrated in humans that the results of the erythromycin breath test, a typical clinical test to evaluate the CYP3A4 activity *in vivo*, were altered by coadministration of rifampicin, a typical

Figure 13.8 Scheme of hepatic transport and metabolism in hepatocytes for the theoretical consideration of overall hepatic intrinsic clearance ($CL_{int,all}$).

OATP inhibitor, and lansoprazole, an MDR1 inhibitor. These findings indicate that the uptake and efflux transport activity of erythromycin affects its overall hepatic intrinsic clearance [65].

For the transporter substrates, detoxification in the liver consists of (1) hepatic uptake from the blood to hepatocytes (PS_{inf}), (2) backflux from hepatocytes to the blood (PS_{eff}), (3) biliary excretion from hepatocytes to bile (PS_{ex}), and (4) metabolism in hepatocytes (CL_{met}) (Fig. 13.8) [66]. In this case, the apparent overall hepatic intrinsic clearance ($CL_{int,all}$) can be described by the following equation.

$$CL_{int,all} = PS_{inf} \frac{PS_{ex} + CL_{met}}{PS_{eff} + PS_{ex} + CL_{met}} \quad (13.12)$$

If PS_{eff} is much lower than the sum of PS_{ex} and CL_{met} , according to Equation 13.12, the overall hepatic intrinsic clearance approximates the intrinsic uptake clearance (PS_{inf}).

$$CL_{int,all} \sim PS_{inf} \quad (13.13)$$

This equation means that the overall hepatic intrinsic clearance is solely dominated by the uptake activity of drugs, even if they are eliminated from the body mainly by metabolism. This situation is often called “uptake-limited clearance.” On the other hand, if PS_{eff} is much greater than the sum of PS_{ex} and CL_{met} , the overall intrinsic clearance can be described as

$$CL_{int,all} = PS_{inf} \frac{PS_{ex} + CL_{met}}{PS_{eff}} \quad (13.14)$$

In this case, the intrinsic clearances of all the processes affect the overall hepatic intrinsic clearance. If drugs can rapidly penetrate the plasma membrane by passive diffusion, we can assume symmetrical membrane transport ($PS_{inf} = PS_{eff}$) and PS_{eff} is

much larger than $PS_{ex} + CL_{met}$. Under these assumptions, the overall hepatic intrinsic clearance described in Equation 13.12 can approximate the metabolic intrinsic clearance (CL_{met}).

$$CL_{int,all} \sim CL_{met} \quad (13.15)$$

It must be noted that the prediction of hepatic intrinsic clearance from *in vitro* metabolic clearance with liver microsomes or cytosol fractions can succeed only in limited situations, even if drugs are metabolized extensively in the liver.

We sometimes define “ β value” according to the following equation.

$$\beta = \frac{PS_{ex} + CL_{met}}{PS_{eff} + PS_{ex} + CL_{met}} \quad (13.16)$$

On the basis of Equation 13.12, $CL_{int,all}$ can be described as

$$CL_{int,all} = PS_{inf} \times \beta \quad (13.17)$$

Thus, β is a kind of indicator representing whether the rate-limiting step of hepatic intrinsic clearance is likely to be an uptake process or not. The β value affects the change in the overall intrinsic clearance when each parameter is altered. Figure 13.9 shows the impact of the β value on the change in the overall intrinsic clearance when PS_{inf} or $CL_{met} + CL_{ex}$ are decreased. When the β value is close to 1, $CL_{int,all}$ approximates PS_{inf} as in Equation 13.13, and thus, a small decrease in the $CL_{met} + CL_{ex}$ value has little effect on the reduction of $CL_{int,all}$. On the other hand, when the β value is small, $CL_{int,all}$ becomes as described in Equation 13.14 and it becomes proportional to the $CL_{met} + CL_{ex}$ value. Therefore, the decrease in the $CL_{met} + CL_{ex}$ value affects the reduction of $CL_{int,all}$ directly. Conversely, a decrease in PS_{inf} value always affects $CL_{int,all}$ to the same degree regardless of the β value because $CL_{int,all}$ is proportional to PS_{inf} as shown in Equation 13.12. These simulation results tell us that the inhibition of influx transporters decreases $CL_{int,all}$ irrespective of the β value, while the inhibition of metabolic enzymes and/or biliary efflux transporters do not always have a direct

Figure 13.9 Impact of the β value on changes in the overall intrinsic clearance. Theoretical calculation of the change in the overall intrinsic clearance ($CL_{int,all}$) of a drug, whose β value is set at a designated value (0.9, 0.5, or 0.2) and is performed when $PS_{ex} + CL_{met}$ (a) or PS_{inf} (b) is specifically decreased to $1/R$.

effect on $CL_{int,all}$, if drugs are substrates of uptake transporters. We must also note that the intrinsic clearance of drugs with a β value of almost 1 can be decreased if CL_{met} or CL_{ex} are suppressed drastically and the β value itself becomes less than 1 after a change in CL_{met} or CL_{ex} (Fig. 13.9).

Watanabe *et al.* [67] have demonstrated that rat *in vivo* biliary and renal clearances with regard to the plasma concentration of several transporter substrate drugs were well predicted from *in vitro* uptake experiments using isolated rat hepatocytes and kidney slices, respectively, except for a few compounds whose renal clearance is very small, possibly because of the involvement of reabsorption. This concept was also successfully applied to human's case [68]. It has been also shown that the *in vivo* $CL_{int,all}$ values of four kinds of statins (pravastatin, pitavastatin, atorvastatin, and fluvastatin), two of which are eliminated from the body by extensive CYP-mediated metabolism, were similar to the uptake intrinsic clearance estimated using the multiple indicator dilution (MID) method in rats or in an uptake assay using cryopreserved human hepatocytes in humans. By contrast, the metabolic intrinsic clearance obtained from an *in vitro* metabolism assay with rat or human liver microsomes considerably underestimated the *in vivo* $CL_{int,all}$ value (Fig. 13.10) [69]. This evidence suggested that the rate-limiting step of hepatic intrinsic clearance of these statins is in the hepatic uptake process and that their β values are expected to be close to 1. Soars *et al.* also indicated that *in vitro* clearance estimated from the disappearance of compounds from the incubation media in an *in vitro* assay using hepatocytes ("media loss" assay) could explain their *in vivo*

Figure 13.10 Rate-determining process of the hepatic intrinsic clearance of statins. The *in vivo* hepatic intrinsic clearances ($CL_{int,all,vivo}$) of four kinds of statins (pitavastatin, fluvastatin, atorvastatin, and pravastatin) in rats and humans are plotted against the uptake clearance or metabolic clearance. Closed circles, predicted from uptake clearance in human cryopreserved hepatocytes; open circles, predicted from metabolic clearance in human liver microsomes; closed squares, predicted from uptake clearance in rats determined using an MID (multiple indicator dilution) method; open squares, predicted from metabolic clearance in rat liver microsomes. The straight line indicates a 1:1 correlation. *Source:* This figure is cited from Ref. 69.

TABLE 13.2 Drugs That are Substrates of Both Metabolic Enzymes and Uptake Transporters

Substrates	Transporter	Metabolic Enzymes
Atorvastatin	OATPs	CYP3A4
Cerivastatin	OATPs	CYP2C8, 3A4
Fluvastatin	OATPs	CYP2C9
Repaglinide	OATPs	CYP2C8, 3A4
Nateglinide	OATPs	CYP2C9, 3A4
Glibenclamide	OATPs	CYP2C9, 3A4
Bosentan	OATPs	CYP2C9, 3A4
Torsemide	OATPs	CYP2C9
Gimatecan	OATPs	CYP3A4
Lopinavir	OATPs	CYP3A4
Docetaxel	OATP1B3	CYP3A4
Telmisartan	OATP1B3	UGTs

hepatic clearance better compared with the use of a conventional assay measuring the metabolite formation clearance with regard to the intracellular unbound concentration of compounds in the hepatocytes. This suggests the importance of uptake transporters in the determination of the overall intrinsic clearance in hepatocytes for some compounds [70,71].

The number of drugs that are substrates of both uptake transporters and are metabolic enzymes and eliminated from the body by extensive metabolism has been increasing gradually, as shown in Table 13.2. The pharmacokinetics of most of these OATP substrate drugs are altered by the coadministration of potent OATP inhibitors such as cyclosporine A and rifampicin and by genetic polymorphisms of OATP1B1 (e.g., T521C) [72,73]. For predicting changes in the pharmacokinetics of these drugs, their β values are essential, but they have not yet been estimated correctly.

Maeda *et al.* [74] have performed a clinical study in humans *in vivo* to demonstrate the rate-limiting step of the hepatic clearance of atorvastatin, a substrate of both OATP transporters and CYP3A4. In this study, a cocktail of a microdose of atorvastatin and of probe drugs for CYP3A4 (midazolam) and hepatic OATPs (pravastatin) was administered simultaneously to healthy volunteers. Changes in pharmacokinetics induced by the coadministration of a selective inhibitor for CYP3A4 [200 mg itraconazole (i.v.)] or for OATPs [600 mg rifampicin (single p.o.)] were observed. As expected, the plasma AUC of midazolam was increased only when it was coadministered with itraconazole, but not with rifampicin, whereas that of pravastatin was increased only by coadministration with rifampicin, but not with itraconazole. These results suggest the selective inhibition of CYP3A4 and OATPs by itraconazole and rifampicin, respectively. Under such conditions, the plasma AUC of atorvastatin was drastically increased by coadministration of rifampicin, but not itraconazole, although the plasma concentration of 2-hydroxy atorvastatin, one of the major metabolites of atorvastatin produced by CYP3A4, was decreased. This suggested that the hepatic clearance of atorvastatin is mainly dominated by hepatic uptake processes mediated by OATP transporters in humans.

13.2.3 Relationship Between Intrinsic Clearance and Organ Clearance

Organ clearance, defined as the rate of elimination of drugs divided by their blood concentration, is dominated not only by tissue intrinsic clearance but also by the blood flow rate in tissues and by the blood unbound fraction. Thus, a change in the tissue intrinsic clearance discussed above does not always lead to a change in organ clearance and subsequent alterations in the blood concentrations of drugs. To consider the effect of change in the intrinsic clearance on the pharmacokinetics of drugs, one of the important factors is the relative contribution of organ clearance to the total clearance (CL_{tot}). In general, drugs are eliminated mainly from the liver and kidney. Therefore, the total clearance can be described as in Equation 13.18.

$$CL_{tot} = CL_h + CL_r + CL_{others} \quad (13.18)$$

Here, CL_h , CL_r , and CL_{others} , respectively, represent the hepatic clearance, renal clearance, and clearance from other organs (if applicable). It is understood that the pharmacokinetics of a drug mainly eliminated from the kidney are changed little even if the hepatic clearance of the drug is largely decreased.

There are several models that relate the intrinsic organ clearance to organ clearance, such as the well-stirred model, the parallel tube model, and the dispersion model. The well-stirred model is used most frequently because of its simple mathematical handling. In this model, there is rapid and complete mixing, hence the term *well stirred*, of drugs coming from the blood circulation and blood in the tissue, and the blood concentration of drugs at the exit of tissue is assumed to be equal to that inside the tissue. In this condition, hepatic clearance (CL_h) can be expressed as in Equation 13.19.

$$CL_h = \frac{Q_h \cdot f_B \cdot CL_{int,h}}{Q_h + f_B \cdot CL_{int,h}} \quad (13.19)$$

Here, Q_h , f_B , and $CL_{int,h}$ represent the hepatic blood flow rate, blood unbound fraction of a drug, and the hepatic intrinsic clearance of a drug, respectively. For the kidney, we must consider the contribution of glomerular filtration, secretion, and reabsorption, and the renal clearance is described as

$$CL_r = \left(f_B \cdot GFR + \frac{Q_r \cdot f_B \cdot CL_{int,r}}{Q_r + f_B \cdot CL_{int,r}} \right) (1 - FR) \quad (13.20)$$

Here, GFR , Q_r , $CL_{int,r}$, and FR represent the glomerular filtration rate, renal blood flow rate, intrinsic renal secretion clearance, and fraction of drug reabsorbed from the urine, respectively.

Let us consider the relationship between intrinsic organ clearance and organ clearance by selecting two extreme cases. When Q_h is much smaller than $f_B CL_{int,h}$, Equation 13.19 is approximated by Equation 13.21.

$$CL_h \sim Q_h \quad (13.21)$$

Thus, hepatic clearance is only dominated by the hepatic blood flow rate, and a change in the hepatic intrinsic clearance does not alter the hepatic clearance

Figure 13.11 The impact of the ratio of $f_B \text{CL}_{\text{int},h}$ to Q_h values on changes in the hepatic clearance (CL_h). This shows a theoretical calculation of changes in the CL_h of a drug, whose $f_B \text{CL}_{\text{int},h}/Q_h$ value is set at a designated value (100, 10, 1, or 0.1) when $\text{CL}_{\text{int},h}$ is decreased to $1/R$.

(“blood-flow-limited clearance”). In contrast, when Q_h is much larger than $f_B \text{CL}_{\text{int},h}$, Equation 13.19 is approximated by Equation 13.22.

$$\text{CL}_h \sim f_B \text{CL}_{\text{int},h} \quad (13.22)$$

In this situation, hepatic clearance is proportional to the hepatic intrinsic clearance. Thus, the change in the hepatic intrinsic clearance should affect hepatic clearance directly (“intrinsic clearance-limited clearance”). Figure 13.11 shows the impact of the ratio of $f_B \text{CL}_{\text{int},h}$ to Q_h on the change in the CL_h value when $\text{CL}_{\text{int},h}$ is decreased. If $f_B \text{CL}_{\text{int},h}$ is larger than Q_h , CL_h approximates Q_h (Eq. 13.21) and it is not changed so much when $\text{CL}_{\text{int},h}$ is decreased. On the other hand, if $f_B \text{CL}_{\text{int},h}$ is larger than Q_h , CL_h approximates $f_B \text{CL}_{\text{int},h}$ (Eq. 13.22) and it is affected directly by a decrease in $\text{CL}_{\text{int},h}$. When drugs are administered orally, if they are eliminated only from the liver, the blood AUC of drugs (AUC_{oral}) can be described by the following equation.

$$\text{AUC}_{\text{oral}} = \frac{F_a F_g \cdot F_h \cdot \text{Dose}}{\text{CL}_h} = \frac{F_a F_g \frac{Q_h}{Q_h + f_B \text{CL}_{\text{int},h}} \text{Dose}}{\frac{Q_h \cdot f_B \text{CL}_{\text{int},h}}{Q_h + f_B \text{CL}_{\text{int},h}}} = \frac{F_a F_g \cdot \text{Dose}}{f_B \text{CL}_{\text{int},h}} \quad (13.23)$$

Here, $F_a F_g$ and F_h represent intestinal availability and hepatic availability, respectively. From Equation 13.23, it should be noted that after the oral administration of drugs, their blood AUC is solely dominated by the hepatic intrinsic clearance, but not by the hepatic blood flow rate, regardless of the rate-limiting step of hepatic clearance.

13.3 PHYSIOLOGICALLY BASED PHARMACOKINETIC MODELING

As discussed above, organ clearance is regulated by multiple factors such as functions of various uptake/efflux transporters and metabolic enzymes. Because the overall

clearance in each organ cannot be described simply as the sum or product of the activity of each molecule, it is necessary to consider the detoxification machineries in each organ and in the body as a *system*. PBPK (physiologically based pharmacokinetic) modeling is one powerful tool that enables us to reconstruct detoxification systems in the body, based on the quantitative functions of multiple molecules and physiological parameters as a mathematical model. Rowland *et al.* [75] first described the clearance concept and a PBPK model for the liver in 1973. Then, as molecules dominating pharmacokinetics have been rapidly cloned and characterized, whole-body PBPK models for several drugs based on the accumulated knowledge of molecules have been constructed and analyzed by many pharmaceutical studies. In a PBPK model, the organs and circulating blood are expressed as compartments and movements of drugs from and to the compartment such as influx, efflux, and metabolism are represented as arrows, and these compartments are connected with the blood flow. Then, several physiological parameters such as organ volume and blood flow rate and drug-dependent parameters such as kinetic parameters for each enzyme and transporter are determined, and differential equations for individual compartments are formulated. Normally, in humans, we can only collect the blood and urine samples to quantify the drug concentration, and the number of sample collections should be limited. Moreover, it is almost impossible to measure the drug concentration in human tissues, which makes it difficult to predict the pharmacological/toxicological effects of drugs. In such situations, once we can construct an appropriate PBPK model, the time-dependent drug concentration in the plasma and all the tissues incorporated into the model can be simulated easily *in silico*. The US FDA clearly recommends the use of dynamic models for the accurate prediction of drug–drug interactions in the process of drug development in its recently published draft guidance about drug–drug interactions (<http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/UCM292362.pdf>). Recently, several FDA-based researchers have published papers showing the importance of PBPK modeling for the drug development. For example, Zhao *et al.* [76] described a number of examples for the use of PBPK models in efficient decision making during a regulatory review at the FDA, and Huang and Malcolm [77] discussed the use of simulation with PBPK modeling to address regulatory questions in clinical pharmacology reviews.

Figure 13.12 shows examples of organ models [78]. If membrane transport of drugs is mainly determined by passive diffusion, and rapid equilibrium of drugs between the blood and organ compartments can be assumed, a single compartment is enough to represent the tissue concentration of drugs as shown in Fig. 13.12(a). Assuming that drugs are well mixed inside a compartment, the blood concentration of drugs inside the tissue is thought to be equal to that at the exit of the compartment. Thus, the differential equations for tissue and the blood compartment can be described as

$$\text{Blood : } V_B \frac{dC_B}{dt} = -Q_T \cdot C_B + Q_T \cdot \frac{C_T}{K_p} \quad (13.24)$$

$$\text{Tissue : } V_T \frac{dC_T}{dt} = Q_T \cdot C_B - Q_T \frac{C_T}{K_p} - f_B \text{CL}_{\text{int}} \frac{C_T}{K_p} \quad (13.25)$$

Here, V_T is the tissue volume, C_T the drug concentration in the tissue, C_B the drug concentration in the blood, Q_T the blood flow rate in the tissue, K_p the tissue-to-plasma

Figure 13.12 Examples of simple models expressing the detoxification ability of organs. (a) Model for drugs whose membrane transport is mainly determined by passive diffusion and where rapid equilibrium between blood and organ can be assumed. (b) Model for drugs that are taken up into organs by active transporters.

concentration ratio, f_B the protein unbound fraction in the blood, and CL_{int} the tissue intrinsic clearance.

On the other hand, if active transport is involved in the membrane permeation of drugs, the inlet and tissue compartments should be separated to represent the membrane transport clearance as shown in Fig. 13.12(b). In this case, the differential equations for blood, inlet, and tissue concentrations are described as in Equations 13.26–13.28.

$$\text{Blood : } V_B \frac{dC_B}{dt} = -Q_T \cdot C_B + Q_T \cdot C_i \quad (13.26)$$

$$\text{Inlet : } V_i \frac{dC_i}{dt} = Q_T \cdot C_B - Q_T \cdot C_i - f_B PS_{inf} \cdot C_i + f_T PS_{eff} \cdot C_T \quad (13.27)$$

$$\text{Tissue : } V_T \frac{dC_T}{dt} = f_B PS_{inf} \cdot C_i - (PS_{eff} + PS_{ex} + CL_{met}) f_T C_T \quad (13.28)$$

Here, V_i is the inlet volume, C_i the drug concentration in the inlet compartment, and f_T the protein unbound fraction in the tissue.

By integrating these equations, the blood and tissue AUCs of drugs are represented as follows [79].

$$AUC_B = \frac{\text{Dose}}{f_B \cdot PS_{inf} \frac{PS_{ex} + CL_{met}}{PS_{eff} + PS_{ex} + CL_{met}}} = \left(\frac{\text{Dose}}{f_B \cdot CL_{int,all}} \right) \quad (13.29)$$

$$AUC_T = \frac{\text{Dose}}{f_T (PS_{ex} + CL_{met})} \quad (13.30)$$

These equations demonstrate important messages about the different changes in blood and tissue concentrations when each intrinsic clearance is altered. As mentioned

in Section 13.2.2, if $PS_{ex} + CL_{met}$ is much larger than PS_{eff} , Equation 13.29 approximates $Dose/f_B PS_{inf}$. Under this condition, when the hepatic uptake activity (PS_{inf}) is decreased, the blood AUC is increased, while the tissue AUC is not changed. Conversely, when the intrinsic clearance of biliary excretion (PS_{ex}) and/or metabolism (CL_{met}) are decreased, the blood AUC is unchanged, whereas the tissue AUC is increased inversely with $(PS_{ex} + CL_{met})$.

Watanabe *et al.* [79] have constructed a PBPK model of pravastatin, which is a substrate of OATPs and MRP2 in the liver (Fig. 13.13(a)). In this model, the liver compartment was divided into five compartments to mimic the dispersion model because the hepatic clearance of pravastatin is very close to the hepatic blood flow rate. The same intrinsic clearance of hepatic influx, backflux, biliary excretion, and metabolic clearance were set up in each segment. Then, all the kinetic parameters were set up only from the results of *in vitro* experiments using a simple scaling-up method. The intrinsic clearances of influx and passive diffusion of pravastatin were determined from uptake studies using isolated hepatocytes, intrinsic clearance of biliary excretion was determined from ATP-dependent transport using canalicular membrane vesicles (CMVs), and metabolic intrinsic clearance was determined from a metabolism assay using the liver S9 fraction. They confirmed the time profiles of the plasma concentration and cumulative biliary excreted amount of pravastatin at several doses in rats and the plasma concentrations after intravenous and oral administration of pravastatin in humans were well reproduced by simulation in this PBPK model. One of the advantages of a PBPK model is in performing sensitivity analysis. This is a good method to identify critical processes dominating the phenotype (e.g., plasma and tissue concentrations) by monitoring any alteration of the target phenotype when specific process is changed *in silico*. Watanabe *et al.* performed the same type of simulation to understand the effects of changes in each intrinsic clearance on the plasma and hepatic concentrations of pravastatin. As shown in Fig. 13.13(b), changes in the influx intrinsic clearance largely altered the plasma concentration but not the hepatic concentration. However, changes in the biliary excretion intrinsic clearance greatly altered the hepatic concentration but not the plasma concentration, which is very similar to the results obtained from the simple model discussed above (Fig. 13.12(b)). A PBPK model also enables us to simulate the severity of drug–drug interactions accurately by connecting the PBPK models of substrate drugs and inhibitors to their target enzymes/transporters. For example, Kanamitsu *et al.* [80] predicted a lethal drug–drug interaction between 5-FU and sorivudine by connecting the PBPK models of 5-FU, sorivudine, and its metabolite, (E)-5-(2-bromovinyl) uracil (BVU). This drug–drug interaction is caused by the mechanism-based inactivation of dihydropyrimidine dehydrogenase (DPD), which is a major metabolizing enzyme of 5-FU, by BVU. As a result, they succeeded in reproducing a great decrease in the hepatic content of active DPD and a subsequent dramatic increase in the plasma concentration of 5-FU by coadministration of sorivudine in an *in silico* simulation. As a whole, by utilizing a PBPK model, we can simulate the plasma and tissue concentrations of drugs in any virtual situation easily by changing the parameters in the model without any additional clinical studies. This greatly helps pharmaceutical researchers to optimize the pharmacokinetic properties of drugs because it is very difficult to estimate the target outcome intuitively from the complicated whole-body drug detoxification system.

Figure 13.13 Simulation of plasma and liver concentration of pravastatin by using a PBPK (physiologically based pharmacokinetic) model. (a) Structure of PBPK model for pravastatin. (b) Simulated time profiles of plasma and liver concentrations of pravastatin when PS_{inf} or PS_{bile} values are increased threefold (broken line) or decreased by one-third (dotted line) compared with the control value (solid line). *Source:* This figure is cited from Ref. 79.

13.4 CONCLUSION

In this chapter, we have overviewed the combinations of molecules responsible for the detoxification of drugs in the liver and kidney and have discussed the quantitative importance of each intrinsic process in the overall performance of detoxification systems from a pharmacokinetic viewpoint. We have also discussed the significant role of the PBPK model for the better understanding of complex systems and quantitatively predicting target outcomes in the process of drug development. Major molecules involved in the detoxification of drugs have already been identified and characterized by *in vitro* assay systems. Thus, we can construct a PBPK model simply by integrating the kinetic parameters of all the molecular-based processes without any empirical parameters. However, the general procedures to set up parameters in any PBPK model from *in vitro* data must be investigated further and validated. Because molecular mechanisms and their networks of pharmacodynamic (PD) processes are very complicated and still not fully understood for most drugs, molecular-based PD models have not been used often, although the concept of mechanistic PK/PD modeling has been established. To construct the correct PD model, it is necessary to have a wide variety of real data sets in different conditions for a thorough validation of the entire complex model because so many parameters dominate the model. Systems biological approaches such as proteomics and metabolomics might help overcome this issue. During the drug discovery and development process, such models representing the molecular systems of detoxification and pharmacological actions of drugs greatly save time and human resources by skipping unnecessary clinical studies. They enable us to predict the pharmacokinetics of drugs in special situations such as with genetic polymorphisms of molecules, drug–drug interactions, and pathophysiological conditions without using any clinical studies. Therefore, general procedures of the construction, data acquisition, and validation of models need to be established.

14.1 INTRODUCTION

Pharmacokinetics (PK) is the science that describes the time course of drug concentration in the body, resulting from administration of a certain drug dose. In comparison, pharmacodynamics (PD) is the science that describes the relationship of the time course of drug concentration and the drug effects in the body [1]. Similarly, toxicokinetics (TK) reveals the toxicity effects as a function of drug exposure. Therefore, PK and TK can be considered biomarkers of drug exposure as well as markers of efficacy and safety. Key determinants of the PK/TK of a drug include absorption, distribution, metabolism, and elimination (ADME) [2]. The current practice of drug discovery and development requires PK and TK analyses from the earliest stages of the program. This assessment is helpful in (i) selection of dose for preclinical toxicity testing and dosage route, (ii) understanding drug exposure, and (iii) identifying dose for first-in-human (FIH) studies and the follow-up clinical trials. Accurate quantitation of drugs in biological media such as blood (usually plasma or serum) and tissues has become more or less a routine with much improved sensitivity via the bioanalytical tools. However,

significant challenges to bioanalysis of potential new chemical entities (NCEs) still lurk in the background, with analytical chemists innovating to address issues.

The purpose of this chapter is to introduce to the fundamentals of PK and TK and their applications in drug discovery and development. It also presents the fundamentals of computational analysis of the data derived from the estimated concentrations in the biological matrices such as plasma. Finally, it discusses the implications of species differences, genomics, and exposure of the metabolites in determining the safe dose in the FIH clinical trials and further identifying clinical dosage regimen.

14.2 PHARMACOKINETIC (PK) ASSESSMENT IN DISCOVERY AND DEVELOPMENT

It is well established that poor drug PK is one of the leading causes of compounds failure in preclinical and clinical drug development [3]. Compounds with poor PK profile tend to have low oral systemic plasma exposure and high interindividual variability, which limits their therapeutic utility [4]. Therefore, a better understanding of the PK profile early on enables the discovery of compounds with druglike properties [5]. In drug discovery settings, the main outcomes of PK/TK assessments are to

- select compounds with the maximum potential of reaching the target
- determine the appropriate route of administration to deliver the drug (typically oral)
- understand how the drug blood levels relate to efficacy or toxicity in order to choose efficacious and safe doses
- facilitate appropriate dose sections for rodent and/or nonrodent species in toxicology testing and drug safety evaluation
- decide on the frequency and duration of dosing in order to maintain adequate drug concentration at target for disease modification
- accurately predict the PK in humans' profile before clinical studies.

A PK/TK study involves dosing animals or humans with NCE and collecting blood samples at predefined time points. After sample preparation and quantification, a concentration–time profile is generated (Fig. 14.1). In drug discovery, preliminary PK studies are usually conducted in rodents to evaluate the extent of drug exposure *in vivo*. This is commonly followed by studies in nonrodents, such as dogs or monkeys, to better characterize the PK profile of the compound and to support safety risk assessment studies. PK scaling, also known as *allometry*, is a discipline that is used to predict human PK profile using preclinical data and is widely used in predicting the drug's half-life, dose, and extent of absorption in humans. This approach is based on empirical observations that various physiological parameters are a function of body size. The allometric methods assume that the same metabolic and disposition processes in the species evaluated are correlated with those observed in humans. However, it has become increasingly realized that, for example, the cytochrome P450 enzymes in the rat are not the same as those in humans and thus may exhibit altered disposition of the compound or even produce different metabolite patterns (Section 14.7). Similarly, uptake and efflux transporters in the animal species may differ in substrate specificity or rate,

Figure 14.1 Estimation of the area under the plasma concentration–time curve (AUC).

as compared to humans, and thus may confound predictions of human PK. Accurate prediction of human PK profile is imperative to minimize drug failure in development because of the PK liability. More detailed description of methods in predicting human PK is beyond the scope of this chapter but can be found in many excellent reviews [6]. An in-depth discussion of various PK concepts and their application can be found in various references [7].

14.3 TOXICITY ASSESSMENT IN DRUG DISCOVERY AND DEVELOPMENT

Several toxicology studies are conducted during early drug discovery and all the way to the late stages of drug development before a New Drug Application (NDA) filing is made. In spite of comprehensive toxicity assessment in early- and late-stage discovery, attrition of NCEs in clinical studies is not uncommon owing to disconnect in predictions of risk in humans on the basis of preclinical data obtained from cell culture and animal models. Nevertheless, extensive preclinical assessment and appropriate scaling and modeling tools will improve predictions. In general, the correlation between human and animal toxicities is good for conditions such as cardiovascular, hematological, and gastrointestinal diseases and the poorest correlation for adverse drug reactions such as, idiosyncratic reactions, skin rash, hypersensitivity, and hepatotoxicity. Toxicology testing in drug discovery is initiated by the high throughput screening, which is followed up by definitive tests. Screening refers to the methods that yield rapid and comprehensive data often using *in vitro* tools. The origin of any toxicological or safety outcome is multifactorial and complex and thus demands for use of sophisticated systems for definitive assessment. Thus, many pharmaceutical companies are also introducing *in vivo* (i.e., animals) toxicology studies as early as possible, quite often in the lead optimization (LO) stage. Extensive and appropriate toxicology studies of varying duration ranging from acute, single dose to chronic, repeat dose in rodent and nonrodent species are needed to establish safe human clinical trials. Acute

toxicity (single dose ranging) studies in preclinical species are performed to support selection of a drug candidate for potential advancement to repeat-dose toxicology studies and ultimately to enable initial FIH clinical trials. The objective of such studies is to identify a dose at which the major adverse effects are observed. These studies are usually carried out in rodents, following a single dose up to a limit of 2000 mg/kg. The information obtained may be translated to select the dose levels for the FIH studies and also to give an indication of potential effects of acute overdose in humans.

Early drug development starts with candidate compound selection. Repeat-dose toxicity studies (7–14 days in duration) in both rodent and nonrodent species are used to better refine safety margins and PK/PD modeling, as well as set appropriate dosages for the subsequent good laboratory practice (GLP) one-month general toxicology and safety pharmacology (i.e., cardiovascular testing in a nonrodent; CNS and respiratory function tests in a rodent) studies that proceed the Investigational New Drug (IND) application before starting FIH clinical trials. TK assessment is based on the multiple samples obtained throughout the duration of the study along with the PK data. Such data are critical in defining a margin of safety between the no observed adverse effect level (NOAEL) and the projected plasma concentrations achieved in human. It is generally considered that a 100-fold safety factor (rodent-to-human exposure ratio) from the most sensitive species NOAEL provides good safety margin in clinical studies. However, our enhanced capability of understanding interspecies sensitivity and detecting more and more subtle effects may warrant a more flexible approach. The toxicology assessment profile includes, for example, the maximum tolerated dose (MTD), safety margins and therapeutic index, target organ toxicities, most sensitive preclinical species, and reversibility of an effect/toxicity. Biomarkers characterization and preclinical to clinical translation can also be investigated in these GLP toxicology studies.

Later drug development includes phases I–IV. Phase I (FIH) starts with a single dose escalation and then multiple dosing in normal healthy subjects. It is used to establish human safety profile and MTD. Phase II defines the efficacy/safety of candidate profile in target patient population (e.g., rheumatoid arthritis), drug–drug interactions, and proof of concept (POC) before proceeding into phase III. Several repeat-dose toxicology studies (general toxicology, embryo-fetal and developmental, fertility, juvenile, carcinogenicity) of longer duration (three months and up to two years) in both rodent and nonrodent species are conducted to support clinical trials of longer duration in patients.

14.4 PARAMETERS THAT DEFINE PK/TK PROFILE

14.4.1 Area Under the Curve (AUC)

AUC is a primary measure of the extent of drug availability to the systemic circulation, that is, it reflects the total amount of unchanged drug that reaches the systemic circulation following intravenous or extravascular administration. Mathematically, area under the plasma (or blood) concentration–time curve (AUC) can be calculated from the obtained concentration–time profile:

$$AUC = \int_0^{\infty} C \cdot dt \quad (14.1)$$

The unit for AUC is concentration per unit time (e.g., ng h/mL). AUC is determined using simple integration method as shown in Equation (14.1) or often by linear trapezoidal method (Fig. 14.1).

The area of each trapezoid is calculated using the following equation:

$$\text{AUC}_{t_1 \rightarrow t_2} = \frac{(C_2 + C_1)}{2} \times (t_2 - t_1) \quad (14.2)$$

The extrapolated area from t_{last} to ∞ , is estimated as

$$\text{AUC}_{t_{\text{last}} \rightarrow \infty} = \frac{C_{\text{last}}}{K_e} \quad (14.3)$$

where C_{last} is the last observed concentration at t_{last} and K_e is the slope obtained from the terminal portion of the curve, representing the terminal elimination rate constant. The total AUC ($\text{AUC}_{0 \rightarrow \infty}$) is determined as

$$\text{AUC}_{0 \rightarrow \infty} = \text{AUC}_{0 \rightarrow t_{\text{last}}} + \text{AUC}_{t_{\text{last}} \rightarrow \infty} \quad (14.4)$$

AUC is used in the calculation of clearance (CL), apparent volume of distribution, and bioavailability (see following sections) and reflects the general extent of exposure over time.

14.4.2 Maximum Plasma Concentration (C_{max}) and Time of Maximum Concentration (T_{max})

C_{max} is defined as the maximum observed drug concentration in the plasma concentration–time profile following intravenous or oral dosing. Most commonly, C_{max} is obtained by direct observation of the plasma concentration–time profile (Fig. 14.1). For some drugs, the pharmacological effect is dependent on the C_{max} ; for example, aminoglycosides, which are widely used antibiotics, need to achieve a C_{max} that is at least 8- to 10-fold higher than that of the minimum inhibitory concentration (MIC) to obtain a clinical response >90% [1]. The unit of C_{max} is concentration unit (e.g., ng/mL).

T_{max} is the time required to reach C_{max} . As with C_{max} , T_{max} is usually determined from direct observation of the plasma concentration–time profile. The unit of T_{max} is time (e.g., h).

14.4.3 Clearance (CL)

CL is a primary parameter that describes the process of irreversible elimination of a drug from the systemic circulation. It is defined as the volume of blood or plasma that is totally cleared of its content of drug per unit time. Thus, it measures the removal of drug from blood or plasma. However, CL does not indicate the extent of drug is being removed but represents the rate, and thus the units are given as mL/min or mL/min/kg (normalized to body weight).

Figure 14.2 Plasma concentration–time profile following IV dosing.

The most widely used approach to evaluate plasma (total) CL involves intravenous administration of a single dose and measuring its plasma concentration at different time points (Fig. 14.2).

$$CL_{tot} = \frac{\text{Dose}_{IV}}{AUC_{IV}} \quad (14.5)$$

In general, a drug is either eliminated unchanged through excretion in the urine and/or bile or by metabolic conversion into more polar metabolite(s) that can be readily excreted in urine and/or bile. Since all these CL mechanisms operate independently, total body CL is a sum of all CLs by individual mechanisms and can be expressed as

$$CL_{tot} = CL_{hep} + CL_{ren} + CL_{bil} \quad (14.6)$$

where CL_{tot} is the total body CL from all different organs and mechanisms, CL_{hep} is the hepatic CL, CL_{ren} is the renal CL, and CL_{bil} is the biliary CL [7].

It is interesting to note that around three-quarters of the top 200 prescribed drugs in the United States are primarily cleared by hepatic metabolism [8]. The hepatic extraction ratio (E_h) is a PK parameter that is widely used to assess the liver's ability to extract drug from the systemic circulation [7]. E_h is defined as the fraction of a drug in the blood that is cleared (extracted) on each passage through the liver and is a function of hepatic blood CL (CL_{hep}) and the hepatic blood flow (Q) [7].

$$E_h = \frac{CL_{hep}}{Q} \quad (14.7)$$

If the predominant CL mechanism for a compound is via hepatic metabolism, then it is reasonable to assume that the CL_{tot} is equal to CL_{hep} . Thus

$$E_h = \frac{CL_{hep}}{Q} = \frac{CL_{tot}}{Q} \quad (14.8)$$

Compounds that undergo hepatic metabolism can be categorized according to their E_h . Compounds with $E_h < 0.7$ are considered high extraction drugs, whereas

compounds with $E_h < 0.3$ are considered low extraction drugs. E_h has a major impact on oral drug bioavailability (see below).

Renal CL (CL_{ren}) can be obtained from the unchanged amount excreted (Ae_{IV}) and plasma AUC (AUC_{IV}) following intravenous dosing [9].

$$CL_{ren} = \frac{Ae_{IV}}{AUC_{IV}} = \frac{Ae_{Oral}}{AUC_{Oral}} \quad (14.9)$$

Similarly, the unchanged amount excreted in urine (Ae_{Oral}) and plasma AUC (AUC_{Oral}) following oral administration can also be used for estimating CL_{ren} .

14.4.4 Apparent Volume of Distribution (V_d)

Volume of distribution (V_d) is a proportionality factor that relates the amount of a drug in the body to its blood or plasma concentrations:

$$\text{Amount of drug in the body at time } t = V_d \times Ct \quad (14.10)$$

Similar to CL, V_d is a primary PK parameter and is represented as volume by unit body weight (e.g., L/kg). V_d is used to assess the extent of drug distribution in the body. This is usually achieved by comparing the drug V_d to the total body water. If the drug has a V_d smaller than the total body water (human total body water = 42 L per 70 kg human body weight), the drug has limited tissue distribution (e.g., naproxen has a $V_d = 11$ L per 70 kg human body weight) [7]. Being proportionality constant, V_d ranges from 3 to more than 40,000 L per 70 kg human body weight and therefore is usually referred to as *apparent volume of distribution*.

14.4.5 Apparent Volume of Distribution at Steady State (V_{dss})

V_{dss} is the volume of distribution that is determined when plasma concentrations are measured at steady state and in equilibrium with the drug concentration in the tissue compartment.

$$V_{dss} = \frac{\text{Amount of drug in the body at equilibrium conditions}}{\text{Steady - state plasma concentrations } (C_{ss})} \quad (14.11)$$

Although V_{dss} is a steady-state parameter, it can be calculated using non-steady-state data as

$$V_{dss} = CL \times MRT \quad (14.12)$$

where mean residence time (MRT) is the average time for all drug molecules to exist in the body. Following intravenous dosing, MRT is calculated as

$$MRT = \frac{AUMC}{AUC} = \frac{\int_0^{\infty} C \cdot t \cdot dt}{\int_0^{\infty} C \cdot dt} \quad (14.13)$$

where AUMC is the area under the first moment versus time curve from time $t = 0$ to ∞ and calculated using trapezoidal rule similar to AUC.

14.4.6 Half-Life ($t_{1/2}$)

Half-life, usually expressed in hours, is the time that is required for the amount (or concentration) of a drug in the plasma to decrease by one half.

$$t_{1/2} = \frac{0.693 \times V_d}{CL} \quad (14.14)$$

Half-life is a dependent PK parameter that is determined by the independent PK parameters, CL and V_d . It is the most widely reported PK parameter since it may constitute a major determinant of the duration of action after single and multiple dosing. In addition, half-life plays a key role in determining the time that is required to reach steady state following multiple dosing and the frequency with which doses can be given.

14.4.7 Bioavailability ($F\%$)

According to the European Medicines Evaluation Agency (EMA), bioavailability ($F\%$) is “the rate and extent to which an active moiety is absorbed from a pharmaceutical form, and becomes available in the systemic circulation.” It is usually determined by calculating the respective AUC after oral and intravenous administrations as

$$\text{Absolute bioavailability} = \frac{AUC_{PO}}{AUC_{IV}} \times \frac{Dose_{IV}}{Dose_{PO}} \quad (14.15)$$

Oral bioavailability is determined by the fraction of dose absorbed (F_a) in the gastrointestinal tract and fraction of dose that does not undergo metabolism in the intestinal tract (F_g) and liver (F_h) (Fig. 14.3) and is expressed as

$$F = F_a \cdot F_g \cdot F_h \quad (14.16)$$

F_h is calculated using the following equation:

$$F_h = 1 - E_h = 1 - \frac{CL_h}{Q} \quad (14.17)$$

Thus, if a drug has a high hepatic extraction ($E_h > 0.7$), then its bioavailability will be low when it is given orally ($F < 0.3$). On the other hand, if a drug has low hepatic extraction ($E_h < 0.3$), then the extent of bioavailability will be high, provided it is completely absorbed and not significantly metabolized by the intestine.

14.5 PK/TK MODELING IN PREDICTING CLINICAL DOSE

PK/TK is an area of science dealing with the exposure of test compound and metabolites, which is determined by the kinetics of exposure, absorption, distribution, metabolism, and excretion. Generally, the extent and duration of exposure are related to the pharmacological or toxicological effects, and thus, the change of the occurrence of the observed effects can be optimized by altering the dose or exposure period.

Figure 14.3 Oral bioavailability is a function of intestinal absorption (F_a), the fraction escaping intestinal metabolism (F_g), and the fraction escaping hepatic extraction (F_h), which occur in series. (See color insert.)

A basis for toxicity assessment is the NOAEL or no observed effect level (NOEL) or low observed effect level. NOAEL represents the highest dose at and below which no significant adverse effects are seen. Owing to ethical and practical reasons, assessment of the NOAEL is derived only from animal toxicity data and extrapolated to identify a clinical dose that is significantly lower than the NOAEL. The same strain and species used in the toxicology studies should be used in the TK studies. Initial studies may involve one sex of each species; however, the use of multiple species is relevant to build confidence in models predicting human effects. Using dose–response relationship, the statistical confidence limits of dose at which the incidence or frequency of a toxic effect is established.

Developing mathematical models is of value only when the mechanisms of toxicity are understood and/or the parameters that are being used in model building have established relationships with the observed toxicity effect. While it is important to understand whether the parent molecule or its metabolite is responsible for toxicity, an estimate of whether humans are of less, equal, or greater sensitivity in comparison to the test species is needed for translating the preclinical data to predict human effects. To establish relationship between exposure and dosimetry, a PK/TK model should incorporate the rate and extent of absorption, compound and/or metabolites distributed in the body, metabolism and kinetics of metabolites (if appropriate), elimination rate and elimination route(s), and the influence of dose on all the above processes (dose dependency).

14.5.1 Noncompartmental Analysis

Various PK parameters such as CL, V_d , $F\%$, MRT, and $t_{1/2}$ can be determined using noncompartmental methods. These methods are based on the empirical determination of AUC and AUMC described above. Unlike compartmental models (see following

section), these calculation methods can be applied to any other models, provided the drug follows linear PK. However, a limitation of the noncompartmental method is that it cannot be used for the simulation of different plasma concentration–time profiles when there are alterations in dosing regimen or when multiple dosing regimens are used.

14.5.2 Compartmental Analysis

Compartmental models of PK analysis are widely used to describe drug distribution and disposition. In these models, the body is assumed to be composed of one compartment or more and the drug kinetics can be defined by differential equations generally of first-order process. These compartments do not have any physiological significance. However, they may represent a group of tissues or organs with similar distribution characteristics. For example, highly blood-perfused body organs such as liver, lungs, and kidney often have different drug distribution than fat tissue.

14.5.2.1 One-Compartment Open Model. One-compartment model, which has gained wide acceptance in TK because of its simplicity, describes the whole body as a single compartment in which the compound is homogeneously distributed following administration (Fig. 14.4). Here, the body is assumed to be a homogeneous unit where the compound is rapidly distributed throughout the body and follows a monoexponential decline. Following intravenous dosing, the plasma drug concentration can be calculated as

$$C = \frac{\text{Dose}}{V_c} \cdot e^{-K_e t} = C^0 \cdot e^{-K_e t} \quad (14.18)$$

where V_c is the volume of compartment, K_e is the rate of elimination, t is time, and C^0 is concentration at time zero.

However, following extravascular administration, the peak plasma concentration is a function of the rate and extent of the absorption as well.

Figure 14.4 One-compartment model.

14.5.2.2 Two-Compartment Open Model. In the two-compartment model, the drug is assumed to distribute into two compartments, the central and the tissue compartments. The central compartment represents the highly blood-perfused body organs where the drug distributes rapidly and uniformly. On the other hand, in the tissue compartment, the drug distributes more slowly (Fig. 14.5).

When the drug concentration versus time profile demonstrates a biexponential decline following intravenous dosing, a two-compartment model that is the sum of two first-order processes (distribution and elimination) will better describe the data (Fig. 14.5). For a drug that follows the two-compartment model, the rate of drug plasma concentration change following intravenous dose can be determined as

$$C = Ae^{-\alpha \cdot t} + Be^{-\beta \cdot t} \quad (14.19)$$

where A and B are functions of the administered dose and α and β are the first-order constants for the distribution and elimination phases, respectively.

In this chapter, only the one- and two-compartment models following intravenous dosing were described. Other models with extravascular dosing have an additional compartment with an absorption rate constant describing input into the central compartment. Models with three or greater compartments may be used if the drug concentration versus time may be described better with additional exponential terms. However, these models have greater complexity.

14.5.3 Physiology-Based Pharmacokinetic (PBPK) Modeling

The accuracy of human prediction will depend on the degree of physiological and biochemical fidelity captured by the model. The advent of structured physiology-based pharmacokinetic (PBPK) models had a dramatic influence on the ability to predict tissue exposure. Such modeling is governed by more fundamental physiological and biochemical processes and is especially useful in estimating tissue exposure, which may be vital in predicting the organ specific toxicity. The major advantages of such modeling are twofold. First, unlike the empirical models (e.g., allometry), the obtained PK parameters are physiologically relevant, and second, concentration–time profiles of

Figure 14.5 Two-compartment open model.

each tissue can be obtained simultaneously. With the exploratory relationships between tissue concentration–time profiles and the pharmacological or toxicological effects, PBPK modeling provides framework for mechanistic PK/PD modeling. Mathematically, the model constitutes of multiple compartments, each corresponding to different body organs or tissues and linked together based on their anatomical placement with respect to blood flow. The vital physiological information in building these models are the tissue volumes, blood flow to the tissue, and the tissue composition. Partition coefficients are measured by equilibrating with tissue homogenates [10]. PBPK models are also most reliable in dose–response and tissue exposure assessments under various physiological conditions (e.g., age, disease condition) [10]. Data collected during a preclinical TK study with focus on time–concentration profiles of compound and its metabolites in plasma and other tissues, facilitates development and validation of comprehensive PBPK models. Such models are useful in assessing the toxicological effects on repeated dose exposure, enzyme induction and inhibition, age- and sex-related physiological factors, and drug–drug interactions, as well as enhance our understanding of interspecies differences.

14.6 TOXICOGENOMICS AND BIOMARKERS

Toxicology safety biomarkers are functional or structural measurements that correlate with a morphologic histopathologic or clinical pathologic change in an organ system such as the liver or heart. Having a translatable biomarker is critical in drug discovery and development. Toxicogenomics is the integration of the *omics* technologies genomics, proteomics, and metabonomics, bioinformatics, and toxicology to better understand drug- or toxicant-induced alterations in biochemical networks (gene, protein, and metabolite) of drug candidate development in a pharmaceutical setting. Therefore, toxicogenomics data can be used as drug toxicity/exposure biomarkers or signatures that provide insights into the toxic mechanism of action of a drug candidate and support safety risk assessment. Such approach can be used in high throughput screening in discovery research. In fact, gene expression is used in the clinic to predict pathologic conditions (e.g., breast cancer), prognosis, and response to therapy. Issues with toxicogenomics experiments are variability in experimental design, strain, gender, age of experimental animals, husbandry, nutrition; interanimal variation; clinical health effects of test compounds; and organs heterogeneity. For example, although the liver appears heterogeneous, it is composed of ~60% hepatocytes, 20% endothelial cells, 15% Kupffer cells, 5% biliary epithelium, and 5% stellate cells.

A good example of the application of toxicogenomics was its use to identify a transcriptional biomarker of the histopathological liver change of oval cell-mediated bile duct hyperplasia (BDH). BDH is a histopathologic finding that occurs in both rodent and nonrodent species. BDH can progress to cholangiocarcinoma with low margins of safety, which can lead to costly, late-stage compound terminations and increased risk to patient safety. Thus, interpretation of the significance of BDH requires consideration of a number of variables, including duration of drug exposure, margins of safety, intended drug indication, and availability of biomarkers to monitor patient safety. The specificity and sensitivity of the discovered candidate biomarker, called *deleted in malignant brain tumor* (DMBT1), was evaluated in livers of rats treated with more than 30 different compounds comprising hepatotoxicities that ranged from BDH and

hepatocyte proliferation to phospholipidosis, hepatocellular vacuolation, apoptosis, and inflammation [11]. Multidisciplinary collaboration between toxicologic pathologists, toxicologists, biologists, personnel in toxicokinetics, and statisticians is needed for successful toxicogenomic efforts.

14.7 SPECIES DIFFERENCES IN DRUG DISPOSITION

Oral exposure of drug molecules is a product of their absorption and hepatic and intestinal first pass. Species differences were reported in the oral exposure of various drug molecules. Several investigators attributed these findings mainly to differences in anatomical and physiological factors such as hepatic blood flow, metabolizing enzyme type, and expression or extent of protein binding. There are significant species differences in bile flow rate and hepatic blood flow (Table 14.1), which may explain some of this variation. In addition, bile composition (acid, ions, electrolytes) also varies between species and may further explain reported species differences in drug biliary excretion rate and thus differences in PK disposition of various drugs [12].

Nelson *et al.* [13] reported that so far 14 CYP gene families have been identified in mammals with significant variations in the primary sequence of amino acids across species. However, these members of the superfamily had highly conserved regions of amino acid sequence. Similar findings were also reported with uridine diphosphoglucose transferases and carboxylesterases [14,15]. Overall, these small differences in the amino acid sequences can lead to significant differences in substrate affinity and specificity, which translate into differences in the metabolism rate and metabolism profiles. As a general rule, compounds with good passive absorption, high rat hepatic extraction ratio, and poor oral bioavailability tend to have better oral bioavailability in higher species such as dogs, monkeys, and humans. There are many cited examples that are consistent with this trend. For example, atomoxetine is a CYP2D6 substrate with an absolute human oral bioavailability of 94% and 63% in poor and extensive metabolizers of CYP2D6, respectively [16]. The moderate to high human oral bioavailability suggests nearly complete oral absorption of atomoxetine. However, preclinical evaluations showed that the absolute oral bioavailability of atomoxetine in rat was only 4% [17] but was 74% in dog [17]. Overall, the disposition of atomoxetine is similar in rats, dogs, and humans with a primary oxidative metabolite of 4-hydroxyatomoxetine that is subsequently conjugated to form 4-hydroxyatomoxetine-*O*-glucuronide. In a

TABLE 14.1 Mean Hepatic Blood Flow and Bile Flow in Selected Species^a

Species	Hepatic Blood Flow (mL/min/Kg)	Bile Flow (mL/min/Kg)
Mouse	73	100
Rat	39	90
Monkey	33	25
Dog	23	12
Human	17	5

^aRef. 18.

radiolabeled study in rats administered ^{14}C -atomoxetine, atomoxetine AUC following oral administration accounted for only 2% of the total ^{14}C AUC as compared to 30% of the ^{14}C AUC following intravenous administration, indicating extensive first-pass metabolism in rats [17]. In a corresponding radiolabeled study in dogs, atomoxetine AUC following oral administration accounted for 33% of the total ^{14}C AUC as compared to 39% of the ^{14}C AUC following intravenous administration, indicating considerably less pronounced first-pass metabolism [17]. This example clearly illustrates the importance of understanding not only the species differences in a drug's metabolic fate but also the extent of species differences in the first-pass metabolism when utilizing preclinical data to project human oral bioavailability.

Indinavir, a CYP3A4 substrate, is an HIV protease inhibitor for which variable oral bioavailability have been observed in preclinical species, ranging from 72% in dogs to 19% in monkeys, and was 24% in rats [18]. This variability was mainly attributed to species differences in the extent of hepatic first-pass metabolism. Chemical and immunochemical inhibition studies indicated the potential involvement of CYP3A isoforms in the metabolism of indinavir in rats, dogs, and monkeys [19], which is consistent with the observation that CYP3A4 is the main isoform responsible for the oxidative metabolism of indinavir in human liver microsomes [19]. The *in vitro* profile of indinavir metabolism was qualitatively similar across species [19]. In addition, an *in vitro*–*in vivo* correlation was established in rats and dogs using the *in vivo* hepatic CL and hepatic first-pass extraction ratio obtained from *in vitro* rat and dog metabolic data, respectively. Based on the *in vitro*–*in vivo* correlation established in rats and dogs, the *in vitro* intrinsic CL of indinavir in human liver microsomes projected a small first-pass metabolism in humans ($E_h = 0.25$), which was consistent with indinavir's high oral bioavailability (60–65%) observed in humans at clinically relevant doses [20]. This example depicts the importance of establishing an *in vitro*–*in vivo* correlation in tested preclinical species so as to use it as a basis to project human CL and oral bioavailability. Overall, these successful medications would not be on the market if the discovery team solely depended on rat oral bioavailability to evaluate their metabolism in humans.

Species differences in the extent of protein binding of various xenobiotics were also reported. It is interesting to note that albeit their structural and functional homologies, there are minor differences in the amino acid sequence in plasma protein molecules such as albumin among various mammals. This may be another contributing factor to the differences in both the binding affinity and sites of drugs in protein molecules among different species [21].

14.8 MIST (METABOLITES IN SAFETY TESTING)

Guidance for Industry on Safety Testing of Drug Metabolites, MIST (METABOLITES IN SAFETY TESTING), was published in 2008 from the Center for Drug Evaluation and Research (CDER) defining the threshold for human metabolites that raise safety concerns as 10% of total drug exposure. Additional guidelines issued from the International Conference on Harmonization (ICH) on Nonclinical Safety Studies for the Conduct of Human Clinical Trials and Marketing Authorization for Pharmaceuticals, ICH M3[R2], define the threshold as 10% of total drug-related exposure, which supersedes when in conflict with the CDER guidance. Others have suggested that

total metabolite burden that accounts for dose is a more relevant threshold [22,23]. Early clinical assessment of human metabolites in plasma or urine enables identification of significant human metabolites and whether they are present at equal or greater exposure levels (AUC) in any one of the preclinical safety species is critical for addressing MIST implications. While rare, this is exceedingly important if the metabolite is formed in humans only. Traditionally, preclinical measurement of circulation concentrations of metabolites only occurs to address specialized cases such as when extensive metabolism of parent drug is expected. When the human metabolite profile is expected to be qualitatively similar to at least one of the preclinical safety testing species, measurement of circulating parent in plasma is adequate in preclinical PK and TK studies. Drug development history has taught us that human drug metabolites can play significant roles in primary and secondary pharmacology, general toxicity, and potentially idiosyncratic drug toxicity (Table 14.2). Therefore, one must develop fit-for-purpose metabolite assessment strategy and use the knowledge of the chemical space of the drug candidate in question, structural activity relationship for both primary and related secondary pharmacology, metabolic CL pathways, and potential target organ toxicity to evaluate if measuring metabolites in preclinical PK/TK samples is warranted and would provide the discovery team with knowledge to design a best-in-class compound. Once a compound has progressed through early development, usually post POC, definitive radiolabeled ADME studies are conducted to identify metabolites and assess the need to monitor these in the clinic or qualify in toxicology studies. Realistically, successful drug discovery teams know well in advance the outcome of these studies.

14.8.1 Pharmacologically Active Metabolites

Metabolism of drug candidates can occur at sites of the molecule that do not alter the active pharmacophore, sometimes even resulting in metabolites that have greater pharmacological activity or longer PD duration. This is usually first suspected when existing PKPD relationships fail to predict the accurate dose required for the desired effect and thus may serve as a trigger for metabolite scouting activities. Prodrug strategies are the intentional design of active pharmacological species from an inactive precursor. Where prodrug approaches achieve quantitative conversion of inactive precursor to the active species, circulating metabolite analysis is the only manner to confirm that dose was administered.

14.8.2 Reactive Metabolites

The MIST guidance addresses a majority of direct or indirect conjugates; the latter class of metabolites is considered harmless, but toxicity continues to be a major challenge

TABLE 14.2 Examples of Human Drug Metabolites that are Known to be Responsible for General Toxicity and Potentially Idiosyncratic Drug Toxicity

Parent Drug	Metabolite	Suspected Metabolite Activity
Acetaminophen	<i>N</i> -acetyl- <i>p</i> -benzoquinone imine (NAPQI)	Toxicity
Troglitazone	GSH conjugation/ring scission	Idiosyncratic toxicity
Losartan	5-Carboxylic acid (10–40 × potency)	Pharmacologically active
Dexfenfluramine	D-Norfenfluramine	Pharmacologically active

leading to drug development failures. Reactive metabolites are frequently suspected when hepatotoxicity or idiosyncratic toxicity is observed. By the very nature of these species, circulating concentrations of reactive metabolites often occur at trace levels, making them difficult to detect and quantitate. Recent strategies to identify reactive metabolites as conjugates to biomolecules such as glutathione or cysteine offer an approach to confirming the formation of these species *in vivo* [24]. Confirming suspected reactive metabolites is informative, and also designing enzymology studies to understand pathways leading to their formation allows an understanding of the potential for species-specific reactions.

14.8.3 Enabling Technologies

Plasma pooling methods were compared to the traditional approaches of obtaining quantitative information on the levels of circulating metabolites in preclinical species. The exposure values obtained via sample pooling are comparable to those obtained by traditional methods of analyzing samples individually. When kinetic information is not needed, this approach allows metabolite identification and exposure burden estimates with a modest resource investment. While metabolite analysis without authentic standards can be accomplished using high resolution or accurate mass LCMS techniques, new techniques using chromatographic measures such as retention time shifting or background subtraction of vehicle-dosed samples offer methods to identify metabolites [25].

There are various approaches to assess the metabolite exposure margin between toxicology species and humans: either by direct or indirect comparison. The preferences in when and how to pursue metabolite assessment is based on the overall development strategy. Therefore, it is important to understand the utility and limitations of analytical instruments in order to apply an appropriate analytical tool to address specific questions posed at different stages of drug development. The urgency of metabolite monitoring depends on the intrinsic nature of the compound, therapeutic intent, and objective of the clinical development; there is not a unified approach that provides efficient resource utilization.

14.9 CONCLUSIONS

PK/TK are important biomarkers of drug exposure, efficacy, and safety in early- and late-stage drug discovery and development. Determinants of a drug PK/TK include ADME. Several toxicity assessment studies (e.g., acute, single, repeat dose studies, GLP) in both rodent and nonrodent species are used to better refine safety margins and PK/PD modeling and set appropriate dosages before starting FIH clinical trials. Critical parameters that define PK/TK profile are AUC, $C_{\max}$, $T_{\max}$, V_d , V_{dss} , $t_{1/2}$, and F . Mathematical modeling can be of great value in the PK/TK evaluation. There is an emerging and increased utility of toxicogenomics to better define drug toxicity/exposure to support compound selection and safety risk assessment. There are significant species differences in the oral exposure to various drugs that must be taken into consideration. Such differences are related to various anatomical and physiological factors including hepatic and renal blood flow, metabolizing enzymes (i.e., CYPs), and protein binding. A valid strategy should be a fit-for-purpose metabolite assessment strategy that uses

the knowledge of the chemical space of a drug candidate being developed, structural activity relationship to pharmacology and toxicology and metabolism CL pathways. Ultimately, a well-designed PK/TK evaluation would provide the discovery team with knowledge to design and advance a best-in-class compound.

15.1 INTRODUCTION

Human absorption, distribution, metabolism, and elimination (ADME) studies are routinely conducted for small molecule drug candidates mostly during the stage of early clinical development to characterize their ADME in the body. Since biological drug candidates, in general, contain only the naturally occurring components of amino acids or nucleic acids, there is no need to perform a human ADME study to understand metabolism and/or elimination for these drug candidates. However, a human ADME study may be desirable for the biological drug candidates that contain chemically modified components such as unnatural amino acids, nucleic acid analogs, or antibody–drug conjugate with small molecule chemical drug complexes.

Pharmacokinetic (PK) evaluation in human ADME study is intended to define the systemic exposure of a drug and its metabolite(s), in particular, pharmacologically active metabolites in the body after dose administration. The most important information of drug and/or metabolite concentration–time profile is to provide the rate and extent of ADME.

Plasma and urine data obtained in human ADME studies can be used to calculate standard PK parameters for unchanged drug, such as time of maximum observed plasma concentration ($T_{\max}$), maximum observed plasma concentration ($C_{\max}$), area under the plasma concentration–time curve from time zero to infinite time ($AUC_{0-\infty}$) or to time of last quantifiable concentration (AUC_{last}), clearance (CL), volume of distribution (V), elimination half-life ($t_{1/2}$), renal clearance (CL_R), and percentage of dose excreted

unchanged in urine. These PK results confirm appropriateness of ADME study design and study conductivity if these results are comparable with the results for the same drug from other previously conducted phase I trials.

To date, two different methods have been used to analyze drug and metabolite kinetics. The first is noncompartmental analysis (NCA), also called *model-independent analysis* of concentration–time profile. This model is not necessarily restricted to the assumption of compartments and is a simple first-order distribution or elimination process. The second approach is compartmental analysis and utilizes mathematical models to describe drug/metabolite behavior in the body, with assumptions of well-mixed compartments and following certain mathematical equations. With the limited assumptions required, NCA allows the estimation of the most basic PK parameters characterizing the ADME processes of a drug. NCA methods are relatively simple to use prevailing in drug development and regulatory evaluation. Nearly all PK analysis of phase I intensive data are completed using NCA. Although NCA provides useful summary assessments of PK parameters, it does not provide some important PK parameters such as rate constants and distribution of drug to different compartments that could help researchers understand mechanisms of drug disposition and action. On the other hand, the mechanistic, model-dependent approach can provide information for a more quantitative understanding of drug action in living cells, organisms, or disease-related targets. Considering that drug development is an information-gathering process of learn–confirm cycles, mechanistic modeling plays an important role in knowledge-based drug development and eventually regulatory approval.

In addition to identifying the major excretory pathways, much can be learned from ADME studies about blood, bile, urine, and feces data of unchanged drug and total radioactivity (TRA). The goal of this chapter is to demonstrate how important information relating to drug ADME may be obtained from the analysis of PK data. The theory and application of PK data analysis and modeling to characterize the PK of a drug and its metabolite(s) based on blood and urine data are presented. The discussion focuses on conventional methods that have been utilized in assessing PK data in human studies.

15.2 RECOVERY OF THE RADIOACTIVE DOSE IN EXCRETA

One of the objectives of a human ADME study is to evaluate mass balance of an administered drug. This type of study provides information on the amount of drug that is recovered over time via the different elimination routes of the body after dose administration. The analyses of radioactivity in excreta sample such as urine, feces, and bile offer information regarding elimination routes of the drug. In human ADME studies, the cumulative excreta samples of urine and feces across the entire study period in each subject are collected following a single oral or intravenous (IV) administration of a radiolabeled drug. For some orally administered drugs, bile samples may also be collected if biliary excretion is expected to be a major route for elimination of drug or its direct conjugates/unstable metabolites that will be converted back to the parent by hydrolysis of the conjugate in the gut microflora. With these samples analyzed, the recovery of the radioactive dose in excreta can be estimated.

It is ideal to have mass balance, that is, near complete recovery with at least 90% of the total administered radioactivity recovered in excreta. A case study using a

Bristol-Myers Squibb drug candidate (BMS-690514) is used as an example of a typical human ADME study and also used to discuss noncompartmental PK data analysis later in this chapter. In the human ADME study of [^{14}C]BMS-69051 [1], an orally administered selective inhibitor of human epidermal growth factor receptors (HERs) and vascular endothelial growth factor receptors (VEGFRs), a single 200-mg dose of [^{14}C]BMS-690514 containing 80 μCi of radioactivity (0.39 $\mu\text{Ci}/\text{mg}$) in a solution of 50 mM citric acid was administered orally to a total of nine healthy male subjects, who were randomly assigned to group 1 ($n = 6$) without bile sample collection or to group 2 ($n = 3$) with bile sample collection. The blood, urinary, and fecal samples were collected up to 216 h postdose and bile samples were obtained from 3 to 8 h postdose by positioning the terminal end of an oral gastroduodenal tube at the vertical limb of the duodenal loop near the ampulla of Vater (confirmed via fluoroscopy). The TRA in excreta was determined by liquid scintillation counting and the concentration of drug-derived ^{14}C radioactivity in individual plasma samples was determined by accelerator mass spectrometry. Following oral administration of [^{14}C]BMS-690514, the mean cumulative recovery of radioactivity over the 0- to 264-h collection interval was 99.98% (Fig. 15.1). The majority of radioactivity, 50%, was recovered in the feces and $\sim 34\%$ was recovered in the urine. For subjects with bile collection, an additional 16% of the dose was recovered in the bile over the 3- to 8-h postdose interval. The excretion rate reached a plateau at 96 h postdose with $<2\%$ daily incremental changes thereafter.

Although there are many ways to increase the chance to achieve a high recovery such as by preventing a labeled fragment of the drug from entering endogenous compound metabolism and prohibiting conversion of the label to a volatile metabolite, it is not unusual to obtain $<100\%$ recovery of the radiolabeled dose in a mass balance study. Beumer *et al.* [2] suggest that total recovery should be at least 90% of the

Figure 15.1 Mean $\pm$ SD cumulative recovery of radioactivity after administration of a single 200-mg (80- μCi) PO dose of [^{14}C]BMS-690514 to healthy male subjects—time course for excretion of radioactivity in urine, feces, bile, and total excreta [1].

administered dose with a 10% margin ($100 \pm 10\%$) as being acceptable. Roffey *et al.* [3] reviewed 171 human mass balance studies and found that 42% had overall recovery values below 90%. If the criteria were dropped to 80%, 15% of mass balance studies would have been considered failures. Low recovery of radioactivity can be explained by biological factors such as binding to specific proteins in tissues, binding to melanin, binding to phospholipids, and covalent and noncovalent binding to tissue. Noncompliance by subjects/study personnel to meticulously collect all excreta samples can also contribute to a low recovery. In general, the drugs with a long half-life tend to show low recovery of administered radioactivity. The success or failure of a mass balance study is dependent on the value of absolute recovery. The acceptance of a mass balance study is ultimately based on achievability of the primary objective of human mass balance study to determine the profile of parent drug and metabolites using excretory and circulatory samples obtained in this study.

15.3 PHARMACOKINETIC ANALYSIS OF BLOOD DATA USING NONCOMPARTMENTAL ANALYSIS

Typically, serial blood samples are collected after single-dose administration of radiolabeled drug in order to characterize the PK of TRA and the drug from plasma or serum concentration versus time profiles in human ADME studies. This allows pharmacokineticists to determine the PK parameters of TRA and a drug by an NCA method without the assumptions of mixed compartments and following certain mathematical equations.

The single-dose PK parameters assessed in human ADME studies, in general, include $T_{\max}$, $C_{\max}$, AUC_{last} , $AUC_{0-\infty}$, $t_{1/2}$, CL/F (apparent total body clearance), and V_{ss}/F (apparent steady-state volume distribution) for an orally administered radiolabeled drug. If a radiolabeled drug is administered via IV injection, the same set of PK parameters will be estimated as for an oral drug, except absolute CL and V_{ss} will be estimated.

The $C_{\max}$ and $T_{\max}$ are obtained from experimental observations. The terminal log-linear phase of the concentration–time curve is identified by least-square linear regression of at least three data points that yielded a maximum G-criterion, which is also referred to as *adjusted R^2* , using no weighting factor. The $t_{1/2}$ value was calculated as $\ln 2/k_{el}$, where k_{el} was the absolute value of the slope of the terminal log-linear phase. The AUC_{0-T} was calculated using the mixed log-linear trapezoidal algorithm with a NCA method. The $AUC_{0-\infty}$ was estimated by summing AUC_{0-T} and the extrapolated area, computed by the quotient of the last observable concentration and k_{el} .

As an example, the mean plasma concentration–time profiles and PK parameters for TRA and BMS-690514 are shown in Fig. 15.2 and Table 15.1, respectively. BMS-690514 was rapidly absorbed with $T_{\max}$ values ranging from 0.5 to 2 h postdose. $T_{\max}$ values for TRA occurred between 1.5 and 4.0 h postdose and reflected a composite plasma concentration–time profile of BMS-690514 and other metabolites in plasma. On the basis of the $AUC_{0-\infty}$ values, the unchanged parent drug, BMS-690514, accounted for $\sim 3.2\%$ and 7.6% of the circulating radioactivity in group 1 (without bile sample collection) and group 2 (with bile sample collection) subjects, respectively, suggesting that metabolites contributed significantly to the circulating radioactivity. Plasma TRA

Figure 15.2 Mean $\pm$ SD plasma concentration–time profile for total radioactivity (TRA) and BMS-690514. Concentrations of drug-derived radioactivity in plasma were determined by accelerator mass spectrometry (AMS); BMS-690514 concentrations were measured with a validated LC-MS/MS assay [1].

was eliminated from the systemic circulation at a slower rate than parent drug, which had a mean $t_{1/2}$ of 16.7 h for the two groups combined. Subjects who went through bile collection had generally lower systemic exposures to TRA than those who did not have bile collection.

15.4 PHARMACOKINETIC ANALYSIS OF URINE DATA

Since renal excretion is an important route of elimination for many drugs, analysis of urinary data can provide useful PK information. Although urine data are less reliable than plasma or serum data for the calculation of PK parameters, together with plasma or serum data, they may allow the calculation of renal clearance. The ratio of a drug excreted unchanged to the TRA excreted in urine is also informative. Comparison of this ratio to the ratio of an unchanged drug to the TRA in plasma or serum may generate insight into drug–metabolite differences in passive/active excretion and reabsorption in the kidneys.

15.4.1 Renal Clearance

Renal excretion is an important route of elimination for many drugs, including unchanged drugs that are primarily excreted in urine and many drug metabolites that are formed by hepatic metabolism of the parent drug. Renal clearance, a useful PK parameter, can be calculated from analysis of urinary data together with plasma data obtained in the human ADME study.

Renal clearance is the hypothetical volume of plasma from which the substance is eliminated by the kidney appearing in the urine per unit time. A physiologic definition of renal clearance (CL_R) is a ratio of the instantaneous urinary

TABLE 15.1 Pharmacokinetic Parameters of Total Radioactivity and BMS-690514 After a Single 200-mg PO Dose of [^{14}C]BMS-690514 to Healthy Subjects in Group 1 (without Bile Collection) and Group 2 (with Bile Collection)

Data are presented as median (minimum, maximum), geometric mean (percent coefficient of variance), or mean $\pm$ SD.

excretion rate (dA_e/dt) and the plasma concentration of drug at the time when the urinary sample is collected (C_p):

$$CL_R = \frac{dA_e/dt}{C_p} \quad (15.1)$$

This equation assumes that urine is collected over a finite period during which the plasma concentration of drug is changing following first-order kinetics. Practically, renal clearance is calculated as the ratio of the amount of drug excreted unchanged ($A_{e(\Delta t)}$) during a urine collection interval (Δt) to the plasma concentration of drug at the midpoint of the interval (C_{mid}):

$$CL_R = \frac{A_{e(\Delta t)}/\Delta t}{C_{mid}} \quad (15.2)$$

By rearranging Equation 15.2, the slope of a linear regression of multiple urine collections ($A_{e(\Delta t)}/\Delta t$) versus C_{mid} is equal to average renal clearance. A short collection period approximates the change in plasma concentration of drug linearly with time but increases the inaccuracy in the estimate of excretion rate due to incomplete bladder emptying. On the other hand, prolonging the urine collection interval can avoid the problem of incomplete emptying. However, the change in drug plasma concentration during a sample collection interval may no longer follow a linear function because the drug plasma concentration is in fact changing exponentially with time under the conditions of Equation 15.1. In practice, a lower limit and upper limit for a collection interval, dt in Equation 15.1 and Δt in Equation 15.2 is ~ 0.5 h [4] or less than an elimination half-life [5].

When taking integration of Equation 15.1 from time 0 to infinity, the numerator dA_e becomes $A_{e(\infty)}$ and the denominator $C_p dt$ is the corresponding area under the plasma concentration–time curve of drug ($AUC_{0-\infty}$):

$$CL_R = \frac{A_{e(\infty)}}{AUC_{0-\infty}} \quad (15.3)$$

Clinically, severe difficulties with compliance in plasma and urine sample collection may occur, especially for drugs with a long terminal elimination half-life as typically a sample collection period of at least five terminal elimination half-lives can be considered to be equivalent to infinite term. Equation 15.3 is practically modified as follows:

$$CL_R = \frac{A_{e(t_2-t_1)}}{AUC_{(t_2-t_1)}} \quad (15.4)$$

On the basis of the plasma and urine data obtained in a human ADME study as presented in Table 15.2 and Figs. 15.3 and 15.4, renal clearance of a drug can be calculated by applying Equation 15.2 or 15.3. The results of the renal clearance calculation using the methods described above are reasonably close to each other at 6.4 L/h. The terminal elimination half-life of this drug is between 10 and 20 h. No practical difficulties occurred in the urine collections taken over an adequate period of five to six terminal elimination half-lives. However, for drugs with a prolonged terminal elimination half-life, more than one month of urine collection will cause compliance issues in the clinical study. In this case, the methods stated by Equations 15.2 and 15.4 gain an obvious advantage over the method approaching infinity.

TABLE 15.2 Plasma and Urine Data and Renal Clearance of a Drug Following a Single IV Administration to a Normal Healthy Volunteer

Time Interval (h)	Amount of Unchanged Drug Excreted in Urine (μg)	Urinary Excretion Rate ($\mu\text{g/h}$)	Mid Plasma Concentration Between Time Interval (ng/mL)	AUC in Plasma Within Time Interval (ng h/mL)	Renal Clearance ^a (L/h)

^aCalculated by equation $\text{CL}_R = \frac{A_{e(t_2-t_1)}}{\text{AUC}_{(t_2-t_1)}}$.

Figure 15.3 Relationship between the urinary excretion rate of a drug and the plasma concentration of the drug at the midpoints of each sample collection interval. The slope of the regression line is equal to the average renal clearance of the drug over 96-h sample collection period. The intercept of the regression line was forced to zero during regression analysis. Renal clearance = 6.43 L/h; $R^2 = 0.9939$.

Figure 15.4 Relationship between the amount of unchanged drug excreted in urine and AUC of drug in plasma within each sample collection interval. The slope of the regression line is equal to the average renal clearance of the drug over 96-h sample collection period. The intercept of the regression line was forced to zero during regression analysis. Renal clearance = 6.37 L/h; $R^2 = 0.9969$.

15.4.2 Fraction of Unchanged Drug Excreted in Urine

The fraction of the amount of drug entering the systemic circulation that is excreted unchanged in urine (f_e) is an important PK parameter that indicates the major pathway of drug elimination through either the excretion of unchanged drug via the kidney or metabolism in the liver followed by the excretion of the metabolite(s) in urine. The value of f_e ranges between 0 and 1.0 depending on the extent to which a drug is renally excreted compared to the overall drug elimination. When the value is low, excretion is a minor pathway of drug elimination, suggesting that the most amount of the drug administered is metabolized. If renal excretion is the major route of elimination, the value of f_e will be higher with an upper limit of 1.0, which means that the renal excretion is the only route of drug elimination. The value of f_e for a particular drug will remain constant independent of the dose of the drug administered via IV injection and is estimated by

$$f_e = \frac{U^\infty}{\text{Dose}} \quad (15.5)$$

where U^∞ is total drug excreted unchanged. If the drug is administered orally, f_e is defined by

$$f_e = \frac{U^\infty}{F \times \text{Dose}} \quad (15.6)$$

where F represents the absolute bioavailability of a drug. In the case of a hypothetical drug with urine and plasma data listed in Table 15.2, the amount of unchanged drug excreted in urine is calculated by multiplying urine drug concentration and the urine volume collected within a time interval, and summing the amount from all intervals, giving the value of 9.997 mg. If the IV dose is 200 mg, the f_e is equal to 0.05. In practice, care should always be taken to ensure collecting urine for at least five elimination half-lives.

In those situations in which total urine collection is impossible, f_e may be estimated by the ratio of renal and total clearances,

$$f_e = \frac{k_{\text{ren}}}{\lambda_z} = \frac{\text{CL}_R \cdot C}{\text{CL} \cdot C} = \frac{\text{CL}_R}{\text{CL}} \quad (15.7)$$

where k_{ren} is the urinary excretion rate constant, λ_z the first-order elimination rate constant, C the plasma drug concentration, CL_R the renal clearance, and CL the total clearance. The CL_R can be estimated from the urine data described in the previous section, while CL can be determined from the plasma data,

$$\text{CL} = \frac{\text{Dose}}{\text{AUC}} \quad (15.8)$$

where AUC is the total area under the plasma concentration–time curve. This calculation of clearance is independent of the shape of the concentration–time profile. For a drug with linear PK, the value of clearance is also independent of dose.

15.5 PHARMACOKINETIC ANALYSIS OF PLASMA DATA WITH COMPARTMENTAL MODEL

The compartmental model approach for analyzing PK data is typically to fit a concentration–time profile with a mono-, bi-, or triexponential equation. Computer fitting concentration–time data obtained from a clinical study, including human ADME study, will provide disposition rate constants, which can be used for estimating more PK parameters such as CL, V , absorption rate constant (k_{01}), and elimination rate constant (k_{10}). Since the number of subjects in human ADME study is limited, the PK data from this type of study are frequently pooled with the data from the other human studies of the drug for determining these PK parameters which can be further used in exposure–response analysis. In this case with a large PK dataset, a population PK approach can be applied to estimate inter- and intrasubject variability in addition to the classic PK parameters. With the variability, the PK of a drug and further the exposure–response correlation, if there is any, can be simulated and predicted for certain dose levels and study outcomes that have not been studied in humans. The most frequently used one-, two-, and three-compartment models are listed in Table 15.3. Since data fitting of concentration–time data is out of the scope of this chapter, readers can reference relevant book [6].

15.5.1 Evaluation of Absorption Kinetics from Plasma Concentration–Time Data

Drug absorption process in the gastrointestinal (GI) tract following oral administration is complex because it involves several processes, including disintegration of a solid dosage form, dissolution of a drug into the gastric fluid, gastric emptying, and the diffusion of a drug molecule across the gut wall. In general, absorption of many drugs after oral administration is assumed to follow a first-order process of which the absorption rate is described by

$$\frac{dA}{dt} = F D k_a e^{-k_a t} \quad (15.9)$$

where A denotes the amount of drug in the body, F the bioavailability, D the dose administered, k_a the first-order absorption rate constant, and t the time. This model predicts fast absorption, a peak concentration with an intermediate plateau around it followed by an exponential decrease showed in a hypothetical plasma concentration–time profile (Fig. 15.5).

Under certain circumstances, plasma concentrations following oral administration sharply increase to a peak at which absorption slows and quickly declines with no intermediate plateau, of which this absorption of drugs is better described by zero-order kinetics:

For $t \leq T$,

$$C = \frac{k_0}{k_{10} V_d} [1 - e^{-k_{10}(t-t_0)}] \quad (15.10)$$

TABLE 15.3 Basic Pharmacokinetic Compartmental Models

Model	Input	Compartment	Elimination Rate	Equation	Compartmental Scheme

2	First-order extravascular	1	First order	$C(t) = \frac{D \cdot k_{01}}{V(k_{01} - k_{10})} (e^{-k_{10}t} - e^{-k_{01}t})$ $k_{10} = \frac{CL}{V}$	<pre> graph LR 0((0)) -- k01 --> 1((1)) 1 -- k10 --> Elimination </pre>
3	IV bolus	2	First order	$C(t) = Ae^{-\alpha t} + Be^{-\beta t},$ $k_{10} = \frac{CL}{V_1}, \quad k_{12} = \frac{CL_{D2}}{V_1},$ $k_{21} = \frac{CL_{D2}}{V_2}$	<pre> graph TD Input -- Bolus IV --> 1((1)) 1 -- k10 --> Elimination 1 <--> k12 2((2)) 2 <--> k21 1 </pre>
4	First-order extravascular	2	First order	$C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-k_{01}t},$ $k_{10} = \frac{CL}{V_1}, \quad k_{12} = \frac{CL_{D2}}{V_1},$ $k_{21} = \frac{CL_{D2}}{V_2}$	<pre> graph LR 0((0)) -- k01 --> 1((1)) 1 -- k10 --> Elimination 1 <--> k12 2((2)) 2 <--> k21 1 </pre>
5	IV bolus	3	First order	$C(t) = Ae^{-\alpha t} + Be^{-\beta t} + Ce^{-\gamma t}$	<pre> graph TD Input -- Bolus IV --> 1((1)) 1 <--> k12 2((2)) 2 <--> k21 1 1 <--> k31 3((3)) 3 <--> k13 1 </pre>

Figure 15.5 Plasma drug concentration–time profile following oral administration of a drug on a linear scale and a semilogarithm scale (inset).

For $t \geq T$,

$$C = \frac{k_0}{k_{10} V_d} [1 - e^{-k_{10}(T-t_0)}] e^{-k_{10}(t-T)} \quad (15.11)$$

where T represents the time at which absorption stops, k_0 the zero-order absorption rate constant, k_{10} the first-order elimination rate constant, V_d the apparent volume of distribution, and t_0 the lag time.

In some cases, plasma concentrations rise quickly to a high level followed with an exponential decrease. The observed data around the peak are underestimated by the first-order absorption. The combination of zero- and first-order input sometimes can give the best fitting to this type of concentration–time profile [7]. Nevertheless, the zero- and first-order absorption processes are mostly observed for many drugs. The Wagner–Nelson (W–N) method, Loo–Riegelman (L–R), deconvolution, nonlinear regression analysis, and several other methods have been used to estimate zero- and first-order absorption kinetics.

15.5.1.1 Wagner–Nelson (W–N) Method. The one-compartment model is based on the assumption that the dose absorbed is distributed into a single compartment and is eliminated from it by first-order process of metabolism and excretion. This is represented schematically in Table 15.3. Following the principle of mass balance, the amount of unchanged drug reaching the fluid of distribution is the amount of drug absorbed at any time, A_t , by the central compartment, the blood stream. The drug absorbed at a given time is equal to the amount of the drug existing in the central compartment plus the amount metabolized and excreted by all pathways and routes. Wagner and Nelson [8,9] derived several absorption equations on the basis of this mass balance for analyzing single-dose one-compartment absorption kinetic data. Since the rates of metabolism and excretion are often found to be directly proportional to the

blood concentration, they proposed that the amount of the drug eliminated by the time t could be estimated by

$$k V_d \int_{t_0}^t C_p dt \quad (15.12)$$

where V_d is the apparent volume of distribution, C_p the plasma concentration of drug at the time when drug is absorbed, and k the first-order rate constant for the elimination of the drug from the body and is equal to the sum of the individual rates of metabolism and excretion. Therefore, integration of the differential mass balance equation over the time range of t_0 and t_∞ results in what has been called *W-N absorption equation*:

$$\left(\frac{A}{V_d} \right)_t = C_p + k \int_{t_0}^t C_p dt \quad (15.13)$$

With Equation 15.13, the amount of the drug absorbed at time t expressed in a concentration unit can be evaluated as being the sum of drug concentration in the systemic circulation and the amount eliminated in a concentration unit. When the time approaches to infinity, the amount of the drug absorbed will asymptotically reach the total amount of the drug absorbed. Since the apparent volume of distribution may not be known without IV PK data, often, Equation 15.13 is represented as the fraction of bioavailable drug absorbed, $(F_{ab})_t$, at time t :

$$(F_{ab})_t = \frac{C_p + k \int_{t_0}^t C_p dt}{k \int_{t_0}^{\infty} C_p dt} = \frac{C_p + k \cdot AUC_{0-t}}{k \cdot AUC_{\infty}} \quad (15.14)$$

To illustrate the procedure for calculating the fraction of bioavailable drug absorbed, a set of concentration–time data following oral administration of a 200-mg dose of drug is listed in Table 15.4 and displayed in Fig. 15.5. The partial AUC_{0-t} value to each time point is calculated by noncompartmental method following the trapezoidal rule. The k value is estimated from the terminal phase of concentration–time profile with a terminal half-life of 8.65 h. As a result of this terminal half-life, the k value is estimated to be 0.0801/h. The product of $k \cdot AUC_{0-t}$ is then calculated and added to the plasma concentration at time t to yield $(A/V_d)_t$. The $AUC_{0-\infty}$ is calculated by the following equation:

$$AUC_{0-\infty} = AUC_{last} + \frac{C_{last}}{k} \quad (15.15)$$

where C_{last} and AUC_{last} are the concentration of drug at the last PK sampling point and the AUC value from time 0 to the last time point, respectively. With known k and $AUC_{0-\infty}$ values, the product of $k \cdot AUC_{0-\infty}$ is obtained. Finally, the fraction of bioavailable drug absorbed is calculated by Equation 15.14 and is presented in Fig. 15.6.

TABLE 15.4 Calculation of Cumulative Fraction of Drug Absorbed Using W–N Method

Time (h)	C_p (ng/mL)	AUC_{0-t} (ng h/mL)	$k \cdot AUC_{0-t}$ (ng/mL)	$C_p + k \cdot AUC_{0-t}$ (ng/mL)	$(F_{ab})_t$
0	0	0	0	0	0
0.5	1.58	0.396	0.147	1.73	0.0357

$k = 0.0801/\text{h}$.

**Figure 15.6** Fraction of bioavailable drug absorbed as function of time after dose.

To utilize W–N method to analyze absorption behavior of a drug, it is not necessary to have IV data available for this drug. The issue with oral PK data alone is inaccuracy in estimating elimination rate constant, k . This is because in some cases, absorption following oral administration is taking place at the same time as drug clearance, tri-exponential drug distribution into the peripheral tissue compartment, or absorption continues well beyond the peak in the concentration–time profile. The mixed distribution and elimination phase frequently shows a longer terminal half-life compared to that following an IV bolus infusion in which the drug is instantly distributed into the blood stream. Therefore, accurate estimate of elimination rate constant has to rely on the PK data following IV bolus infusion.

15.5.1.2 Loo–Riegelman (L–R) Method. When a drug has been administered intravenously first, then extravascularly second, disposition of the drug shows bi- or triexponential. Loo and Riegelman [10] have proposed a mathematically and physiologically more acceptable method to conceive the body to be a two-compartment open system. The scheme and equation for this type of model are presented in Table 15.3.

It is convenient to express all the drug amounts as concentration terms by dividing by V_p , whereupon they become the concentrations in central (C_p) and tissue (C_t) compartments as well as the concentrations of metabolized and excreted drug (C_{me}). Therefore, C_{me} up to time t becomes

$$(C_{me})_{in} = k_{10} V_d \int_{t_0}^t C_p dt \quad (15.16)$$

Integration of the differential equation between the time limits of 0 and t obtains

$$\left(\frac{A}{V_p} \right)_{in} = (C_p)_{in} + k_{10} V_d \int_{t_0}^t C_p dt + (C_t)_{in} \quad (15.17)$$

This is a form of modified W–N equation for the two-compartment model. Taking the similar approach to W–N equation, the fraction of bioavailable drug absorbed, $(F_{ab})_t$, through a first-order process and eliminated through a second-order process at time t becomes

$$(F_{ab})_t = \frac{C_p + C_t + k_{10} \int_{t_0}^t C_p dt}{k_{10} \int_{t_0}^{\infty} C_p dt} = \frac{C_p + C_t + k_{10} \cdot AUC_{0-t}}{k_{10} \cdot AUC_{\infty}} \quad (15.18)$$

The concentration of drug in the central compartment C_p can be determined with plasma samples using a validated bioanalytical method. However, the concentration of the drug in peripheral (tissue) has to be estimated from the distribution rate constants between central and peripheral compartments with an assumption of a linear function on drug concentrations in the central compartment between two mostly closed time points. After approximation, the differential equation of

$$\frac{dC_t}{dt} = -k_{21} C_t + k_{12} C_p \quad (15.19)$$

becomes integratable by Laplace transforms and the second term of the equation can be simplified by a two-term Taylor approximation. Therefore, the concentration of drug in tissue compartment can be estimated by the following equation:

$$(C_t)_{t_n} = \frac{k_{12} \cdot \Delta C_p \cdot \Delta t}{2} + \frac{k_{12}}{k_{21}} (C_p)_{t_{n-1}} \cdot (1 - e^{-k_{21} \cdot \Delta t}) + (C_t)_{t_{n-1}} \cdot e^{-k_{21} \cdot \Delta t} \quad (15.20)$$

where t_n and t_{n-1} are the sample times for samples n and $n - 1$, respectively, $(C_p)_{t_{n-1}}$ is the concentration of drug at the central compartment for samples $n - 1$ and $(C_t)_{t_n}$

and $(C_t)_{n-1}$ are the concentrations of drug at the tissue compartment for samples n and $n - 1$, respectively.

15.5.1.3 Gamma Model of Absorption. Absorption of some drugs that show flat and delayed absorption profiles with a correlation between delay and peak width may not obey the zero- or first-order absorption model described above. A gamma model that describes an asymmetric S-shaped curve with an early flat phase was developed by Debord *et al.* [11] to predict oral cyclosporin PK profile:

$$\frac{dA}{dt} = FD \cdot f(t) \quad (15.21)$$

$$f(t) = \frac{b^a}{\Gamma(a)} t^{a-1} e^{-bt} \quad (15.22)$$

where dA/dt denotes the absorption rate at time t , a the number of sequential compartments connected by an identical input rate constant b (Fig. 15.7), and Γ the gamma function defined by

$$\Gamma(a) = \int_0^{\infty} x^{a-1} e^{-x} dx \quad (15.23)$$

The convolution of the absorption rate at time t dA/dt with the impulse response of a two-compartment model gives the equation for drug blood concentration at time t :

$$I(t) = A_1 e^{-\lambda_1(t)} + A_2 e^{-\lambda_2(t)} \quad (15.24)$$

where $I(t)$ is the concentration at time t following, A_1 and A_2 are the disposition coefficients, and λ_1 and λ_2 are the disposition rate constants.

Figure 15.8 shows an example in which a good fit is obtained with the gamma function, whereas a poor fit is obtained with a classic exponential model with lag time.

Figure 15.7 Gamma distribution model as a sequence of identical compartments (a) connected by an equal rate constant (b) with an input toward a central compartment followed with a distribution process between the central compartment and peripheral compartment and with a linear elimination process from the central compartment.

Figure 15.8 Comparison of gamma absorption and a classic exponential with lag-time models.

15.5.1.4 Discontinuous Absorption Model. Delayed gastric emptying of a portion of an orally administered dose can cause double peaks or irregular shape in the absorption and early distribution phases of concentration–time profiles. The factors other than delayed gastric emptying, such as enterohepatic recirculation, storage, and subsequent release of drug from a postabsorptive depot site, may also be responsible for the double peaks. However, the second peak under these circumstances may occur in the distribution phase of the concentration–time profile. A discontinuous absorption model has been developed to describe a drug absorption process along the gastric tract with distinct double peaks in the early phase of concentration–time profile.

The discontinuous absorption model [12] assumes that two absorption sites exist separately in the GI tract. The entire dose is loaded into the first gut compartment with a zero-order input and the drug in the first gut compartment transfers to the second gut compartment, which is the first absorption site. Absorption to the central compartment does not take place in intervening regions between the two absorption sites. When the entire drug moves to the second absorption site, absorption ceases. The amount of drug entering the first absorption site is dependent on the dose and the rate of drug entering the site (k_1). The transition rate (k_t) into the second absorption site is dependent on the efficiency of the first absorption site, the distance between the two absorption sites, and the transition rate in the nonabsorption regions of the gut. All rate constants in the discontinuous model, including transition rate constants in the gut (k_1 and k_t), absorption rate constants (k_{a1} and k_{a2}), and elimination rate constant (k_{10}) are assumed to be first-order rate constants (Fig. 15.9). The equation to describe the fraction of drug in each compartment is solved using Laplace transforms. The drug in central compartment is given by

$$L(A_C) = \frac{[k_{a1} \cdot L(A_2) + k_{a2} \cdot L(A_N)](s + k_{21})}{[(s + k_{21})(s + k_{10} + k_{12})] - k_{21} \cdot k_{12}} \quad (15.25)$$

where $L(A_C)$, $L(A_2)$, and $L(A_N)$ are the Laplace transforms for drug flux in the central compartment and the two absorption compartments, respectively, and s is the Laplace operator.

Figure 15.9 Discontinuous oral absorption pharmacokinetic model.

The ratio of the absorption rate constant at one specific site to the sum of all rate constants in this absorption compartment represents the theoretical fraction of drug absorbed at this site. For example, the fractions of drug absorbed at the first and second absorption sites F_1 and F_2 , respectively, are as the follows [12]:

$$F_1 = \frac{k_{a1}}{k_t + k_{a1}} \quad (15.26)$$

$$F_2 = \frac{(1 - F_1)k_{a2}}{k_t + k_{a2}} \quad (15.27)$$

The simulated effect of changes in the number of gut compartments (N), transition rate constant (k_t), and absorption rate constants (k_{a1} and k_{a2}) are plotted in Fig. 15.10. As N increases, the time to reach the second peak is delayed and the concentration in the second compartment decreases. Where the k_t value becomes large, the second peak occurs shortly after the first peak and the fraction of drug absorbed from both the absorption sites is also reduced. The values of k_{a1} and k_{a2} determine the height of these two peaks. The high absorption rate produces a high peak associated with this absorption process.

Figure 15.10 Simulated concentration–time profile following oral administration of a hypothetical drug based on a discontinuous gastrointestinal absorption model [12]. (a) Influence of the total number of gut compartments (N). (b) Influence of drug transition rate (k_t) between absorption sites. (c) Influence of the fraction of drug absorbed at the first and second absorption sites.

Figure 15.11 Parallel oral absorption pharmacokinetic model.

15.5.1.5 Parallel Absorption Model. When two or more concentration peaks are not distinct in a concentration–time profile, a parallel absorption model can be used to fit these PK data. Figure 15.11 shows the scheme of a dual absorption pathway model with two different first-order absorption rate constants (k_{a1} and k_{a2}) and two different lag times. The drug administered enters two different gut compartments with the different fractions of dose, F and $1 - F$, divided into the rapidly and delayed absorbed subdoses. The drug in the gut compartments is then absorbed into the central compartment in which the drug is either exchanged between the central compartment and two different peripheral compartments or eliminated from the central compartment. A two-compartment model may fit the two-peak concentration–time profiles with less precise parameter estimates due to underparameterization. A three-compartment model is in general superior to the two-compartment model in fitting the slowly declining terminal phase of concentration–time data. The three-compartment model with two parallel absorption processes schematically depicted in Fig. 15.11 was used to describe the PK of piperazine administered with concomitant CV8 [13].

In summary, a delayed peak or multiple peaks that are not so uncommon atypical absorption phenomena after oral drug administration may occur due to the delayed release of drug from its dosage form, cyclical gastric emptying, or influences by intake of food. The clinical implication of these atypical absorption processes should be considered. The compounds with a delayed peak may not be suitable as a medication to treat disorders where rapid $t_{\max}$ and high $C_{\max}$ are important in clinical efficacy. Compounds with multiple peaks may cause some safety issues, especially for those drugs with a narrow therapeutic index.

15.5.2 Evaluation of Distribution Kinetics from Plasma Concentration–Time Data

Drug distribution in the body can be influenced by different processes, including entero-hepatic recirculation, various transport mechanisms, and drug binding to tissue and proteins as well as metabolism. In some cases, the distribution curve of drugs is significantly affected by these processes so that the normal pattern of smooth decreases

Figure 15.12 The enterohepatic recirculation model consists of a central compartment, a peripheral compartment, and the circulation chain that includes three compartments each of fixed volume.

in plasma concentrations does not exist, resulting in double peaks or multiple peaks when enterohepatic recirculation is the primary process of drug distribution. The typical compartmental models are no longer applied to this type of distribution. More complex PK models are needed to predict drug concentration in circulation that will provide useful information regarding optimal dosing and potential exposure–response correlation.

15.5.2.1 Modeling Enterohepatic Recirculation. The drugs that experience enterohepatic recirculation will show at least two peaks in the plasma concentration–time profile. After oral administration, a dose D reaches the absorption compartment (GI tract). A fraction of the dose is absorbed by a first-order process reaching the central compartment. The drug absorbed is distributed from the central compartment 1 to the peripheral compartment 2 and is eliminated from the central compartment 1 by first-order process if the concentration–time profile can be described by a two-compartment model. Some fraction of the dose absorbed in the central compartment will be added back to the systemic circulation at time τk as a secondary input into the systemic circulation (Fig. 15.12). A two-compartment PK model incorporated with enterohepatic recirculation is as follows [14]:

$$C_j(t) = C_{\text{pred},j}(t) + \delta_1 \cdot C_{\text{pred},j}(t - \tau_1) + \delta_2 \cdot C_{\text{pred},j}(t - \tau_2) + \cdots + \delta_n \cdot C_{\text{pred},j}(t - \tau_n) + \varepsilon_j(t) \quad (15.28)$$

where $C_j(t)$ and $C_{\text{pred},j}(t)$ are the measured and predicted concentrations for the j th subject at time t , respectively, and δ fraction of drug due to enterohepatic recirculation is added back to the systemic circulation at time τk where k is the number of events. An assumption is held for this model that a drug accumulates in a certain compartment or compartments and retains there for some time, then it returns into the circulation system, which eventually results in the second peak of $C_j(t)$. The phenomenon of the second peak in the distribution phase has been observed in species that have a gall bladder, when hepatic recirculation of drug occurs as periodical release of bile into the duodenum with subsequent reabsorption of drug into the circulation system. Random effects, ε , were supplemented to the fraction that will be added back to the circulation and the gall bladder emptying time to account for variability. The model using the nonlinear mixed-effects function provided a good fitting of most individual

Figure 15.13 Plasma ezetimibe concentration–time profiles with enterohepatic recirculation after multiple-dose administration of ezetimibe [14].

plasma concentration–time profiles for ezetimibe following dose administration [13] and is presented in Fig. 15.13.

15.5.2.2 Modeling Blood–Brain Barrier Transport. Compartmental PK analysis has been applied to characterize the drug concentration–time course in systemic circulation and the brain extracellular fluid (bECF) simultaneously with the advantage over traditional noncompartmental methods where the compartmental analysis quantifies the rate of blood–brain barrier (BBB) transport independent of differences in systemic exposure. This allows comparison of *in vivo* with *in vitro* PK parameters and comparison between compounds that have different systemic PK properties. Furthermore, modeling the bidirectional distribution to and from the brain may reveal the process that determines the time course of drug effect to help design preclinical and clinical studies and interpret pharmacological data from these studies.

A two-compartment model in systemic circulation connected to a one-compartment brain model that is separated by a BBB was proposed to fit unbound plasma and bECF escitalopram concentrations simultaneously in rats [15]. This structure of the model is depicted in Fig. 15.14. Using intracerebral microdialysis, quantitative information about the free drug concentrations at the extracellular target site in the discrete areas of the rodent brain can be obtained. The general differential equations associated with this model are as follows:

$$\frac{dC_1}{dt} = \frac{\text{input}}{V_1} + \frac{k_{21}C_2V_2}{V_1} + \frac{k_{\text{out}}C_{\text{bECF}}V_{\text{bECF}}}{V_1} - (k_{10} + k_{12} + k_{\text{in}})C_1 \quad (15.29)$$

$$\frac{dC_2}{dt} = \frac{k_{12}C_1V_1}{V_2} - k_{21}C_2 \quad (15.30)$$

$$\frac{dC_{\text{bECF}}}{dt} = \frac{k_{\text{in}}C_1V_1}{V_{\text{bECF}}} - k_{\text{out}}C_{\text{bECF}} \quad (15.31)$$

where C_1 and C_2 denote the drug concentrations in the central and peripheral plasma compartments and C_{bECF} is the extracellular concentration in the brain. Input represents

Figure 15.14 Compartmental model of drug transport between plasma and brain extracellular fluid following intravenous injection.

Figure 15.15 Observed (mean) and model-predicted unbound escitalopram concentration–time profiles in plasma (filled symbols) and brain extracellular fluid (open symbols) following intravenous infusion of 2.5-, 5-, and 10-mg/kg escitalopram [15].

the administered dose via IV injection. The k and V signify the rate constant and volume of distribution as detailed in Fig. 15.14. This model was successfully fit to the unbound escitalopram concentration–time profiles in plasma and bECF obtained in an experiment in rats (Fig. 15.15).

Solving the compartmental model provides both the extent and rate of drug transport to brain. The extent of equilibrium across the BBB is influenced by the involvement of active membrane transport mechanisms located at the endothelial cells in the BBB, whereas the rate of drug transport across the BBB is related to physiochemical properties of drug. These PK characteristics will affect the degree, onset, and duration of the

centrally mediated effect. A final BBB model is established on the basis of an iterative analysis of the experimental data using a variety of different models. Both systemic and brain models vary from one- to multiple-compartments and from a linear model to a nonlinear model such as Michaelis–Menten (M–M) model. The goodness-of-fit is employed to select the best model for fitting the experimental data.

15.5.3 Evaluation of Metabolism Kinetics from Plasma Concentration–Time Data

15.5.3.1 Compartmental Analysis of Metabolites. The data analysis of metabolite plasma concentration–time data using a compartmental approach is similar to the analysis for the disposition of parent drug in systemic circulation. Compartmental modeling to include metabolites is more complicated than that for parent drug alone because this type of model need not only characterize parent drug but also requires a link between parent and metabolite as well as possible involvement of nonlinear kinetics. For modeling with parent drug only, the methodical, conceptual, and computational uniformity in modeling various linear biological systems is the dominant characteristic of the linear system approach technology. However, saturation of the metabolic reaction results in nonlinear kinetics.

Figure 15.16 represents an integrated open two-compartment model for a parent drug and an open one-compartment model for the metabolite of the parent drug. Assuming

Figure 15.16 A compartment model in which a parent drug is characterized by a two-compartment model and a metabolite is assessed by a one-compartment model. A_{p1} and A_{p2} are the amount of a parent drug in the central compartment and peripheral compartment, respectively. A_m is the amount of the metabolite in the central compartment of the metabolite.

both input and disposition functions are linear, the model can be solved by the Laplace transform with a general fraction theorem. The amount of parent drug (A_{p1}) in the central compartment may be written [16]:

$$A_{p1} = \frac{(k_{20}k_{21} - \alpha)(k_{31} - \alpha)D}{(\beta - \alpha)(\gamma - \alpha)}e^{-\alpha t} + \frac{(k_{20}k_{21} - \beta)(k_{31} - \beta)D}{(\alpha - \beta)(\gamma - \beta)}e^{-\beta t} + \frac{(k_{20}k_{21} - \gamma)(k_{31} - \gamma)D}{(\alpha - \gamma)(\beta - \gamma)}e^{-\gamma t} \quad (15.32)$$

where α , β , and γ are coefficients of the powers, $k_{i,j}$ is the first-order rate constant describing transfer from compartment i to compartment j , t is the time postdose, and D is the dose. The amount of metabolite (A_m) in the central compartment can be expressed as follows:

$$A_m = \frac{k^\circ(k_{20}k_{21} - \alpha)(k_{31} - \alpha)(1 - e^{ab})}{-\alpha(\beta - \alpha)(\gamma - \alpha)}e^{-\alpha t} + \frac{k^\circ(k_{20}k_{21} - \beta)(k_{31} - \beta)(1 - e^{\beta b})}{-\beta(\alpha - \beta)(\gamma - \beta)}e^{-\beta t} + \frac{k^\circ(k_{20}k_{21} - \gamma)(k_{31} - \gamma)(1 - e^{\gamma b})}{-\gamma(\alpha - \gamma)(\beta - \gamma)}e^{-\gamma t} \quad (15.33)$$

where k° is zero-order infusion rate in units of amount per time and b the time when infusion ends. The above equation applies when the infusion begins at a time zero. For continuous infusion, b is equal to t and varies with t . When infusion ends, b becomes constant corresponding to the duration of infusion. In the above model, drug metabolism is described by linear models assuming the concentration of the involved enzyme is high with respect to the drug concentration. However, in many cases, drug concentration in systemic circulation is much higher than enzyme concentration at a metabolic reaction site. This leads to saturation of drug at the enzyme reaction sites, resulting in zero-order kinetics. While drug concentration is at intermediate level, the M–M equation, a nonlinear model, appropriately describes drug disposition, as discussed in Section 15.5.4.3.

A parent–metabolite model was developed to assess the disposition of artesunate (AS) and its active metabolite dihydroartemisinin (DHA) in healthy subjects receiving single or multiple dosing of AS orally [17]. The structure of the model is depicted in Fig. 15.17, which consists of a one-compartment model with first-order absorption and first-order elimination describing the AS concentration–time profile and a two-compartment model with one central and one peripheral compartment for DHA. With this model, the data for both AS and DHA were analyzed simultaneously with a population PK approach nonlinear mixed effects modelling (NONMEM). The model was stable and was able to predict AS and DHA concentration–time data following single and repeat dosing of oral AS equally well.

15.5.3.2 Compartmental Analysis of Drug–Drug Interaction. Concomitantly administered drugs often cause one-direction or mutual impact by increasing or decreasing the systemic exposure of drugs. As a result of the interaction, the probability of causing adverse events may be higher due to increased drug concentration in blood or efficacy of the affected drug may decrease with lowered plasma drug concentration. In human drug–drug interaction (DDI) studies, both parent drug and metabolite

Figure 15.17 Scheme of a parent-metabolite model following oral administration of a parent drug. A_{p1} is the amount of a parent drug in the central compartment. A_{m1} and A_{m2} are the amount of the metabolite in the central and peripheral compartments of the metabolite, respectively. k_a is the absorption constant. k_{p10} and k_{m10} are the elimination rate constants for the parent and the metabolite, respectively. k_{m12} and k_{m21} are the distribution rate constants for the metabolite.

plasma concentration-time profiles may be assessed simultaneously. Evaluation of the PK parameters of the parent drug and its metabolite(s) can provide information on DDI. In an example presented below, the mutual effect of two anticancer agents thiotepa (TT) and cyclophosphamide (CP) is evaluated by a compartment PK model [18].

The prodrug (CP) is metabolized and bioactivated by CYP isoenzymes to form 4-hydroxycyclophosphamide (HCP) that exerts cytotoxicity in the target cells [18]. The resulting metabolite, HCP, is further metabolized to phosphoramidate mustard (PM). These metabolites induce CYP enzymes through a process called *autoinduction*. CP is also metabolized through a noninducible side-chain oxidation, resulting in the formation of 2-dechloroethylcyclophosphamide. On the other hand, TT is metabolized to its main metabolite tepa (T) mediated by CYP2B and 2C. T has pharmacological properties similar to parent TT. When CP is coadministered with TT, the latter inhibits the CYP enzymes responsible for the biotransformation of CP to HCP, resulting in a decrease in HCP concentrations. Meanwhile, CP increases the rate of metabolism of TT to T. These processes represent a mutual DDI between CP and TT and make PK modeling more complicated.

The compartment PK DDI model is schematically pictured in Fig. 15.18. In this model, 2 two-compartment models with first-order elimination from the central compartments of TT and T, respectively, are used to characterize the concentration-time profiles of both TT and T. TT as a perpetrator inhibits CYP enzymes so that bioactivation from CP to HCP is reduced [18]. A two-compartment model and a one-compartment model describe the PK profiles of CP and HCP, respectively. Elimination from the central compartment of CP consists of two pathways, a noninducible route and an inducible route of which the latter leads to the formation of HCP. Both models to describe the time course of CP and TT include two different hypothetical enzyme compartments. In the first hypothetical enzyme compartment, the time course of CP autoinduction is modeled. Biotransformation from CP to HCP is directly proportional to the amount of enzyme in this compartment, whereas TT produces inhibition to

Figure 15.18 Integrated two-compartment models for mutual drug–drug interaction between cyclophosphamide and thiotepa [18].

the metabolism. In the second hypothetical enzyme compartment, an enzyme turnover model, including a zero-order enzyme formation model and a first-order enzyme elimination model, appropriately describes TT and T data. Enzyme elimination is inhibited in the presence of CP with an E_{max} model. When CP infusion starts, the amount of enzyme in the second hypothetical enzyme compartment begins increasing until a maximum amount of enzyme is reached as a result of decreased enzyme elimination by CP. The differential equations describing the mass transport of the different compartments of the model are as follows [18].

Differential equations for the central compartments:

$$\frac{dA_{CP1}}{dt} = R_{CP} - \frac{CL_{nonindCP}A_{CP1}}{V_{CP}} - \frac{CL_{indCP}A_{CP1}A_{ENZCP}}{V_{CP}} - k_{CP12}A_{CP1} + k_{CP21}A_{CP2} \quad (15.34)$$

$$\frac{dA_{TT1}}{dt} = R_{TT} - \frac{CL_{nonindTT}A_{TT1}}{V_{TT}} - \frac{CL_{indTT}A_{TT1}A_{ENZTT}}{V_{TT}} - k_{TT12}A_{TT1} + k_{TT21}A_{TT2} \quad (15.35)$$

$$\frac{dA_{HCP}}{dt} = \frac{CL_{indCP}A_{CP1}A_{ENZCP}}{V_{CP}} - k_{HCP}A_{HCP} \quad (15.36)$$

$$\frac{dA_{T1}}{dt} = \frac{CL_{indTT}A_{TT1}A_{ENZTT}}{V_{TT}} - k_{T12}A_{T1} + k_{T21}A_{T2} - k_TA_{T1} \quad (15.37)$$

Differential equations for the peripheral compartments:

$$\frac{dA_{CP2}}{dt} = k_{CP12}A_{CP1} - k_{CP21}A_{CP2} \quad (15.38)$$

$$\frac{dA_{TT2}}{dt} = k_{TT12}A_{TT1} - k_{TT21}A_{TT2} \quad (15.39)$$

$$\frac{dA_{T2}}{dt} = k_{T12}A_{T1} - k_{T21}A_{T2} \quad (15.40)$$

Differential equations for the enzyme compartments:

$$\frac{dA_{ENZCPact}}{dt} = \frac{k_{CPenz}C_{CP1}}{IC_{50} + C_{CP1}} - k_{inh}A_{TT1}A_{ENZCPact} + k_{reac}A_{ENZCPinact} \quad (15.41)$$

$$\frac{dA_{ENZCPinact}}{dt} = k_{inh}A_{TT1}A_{ENZCPact} - k_{reac}A_{ENZCPinact} \quad (15.42)$$

$$\frac{dA_{ENZTT}}{dt} = k_{TTenz} - k_{TTenz} \left(1 - \frac{E_{max}C_{CP1}}{IC_{50} + C_{CP1}} \right) A_{ENZTT} \quad (15.43)$$

where all the parameters in the differential equations are explained in Fig. 15.18.

This integrated model describes the mutual DDI between CP and TT successfully at the level of enzyme kinetics as shown in Fig. 15.19 where model-predicted concentrations and individual-predicted concentrations of CP, HCP, TT, and T are adequately fitted the corresponding observed concentrations analyzed with a population PK approach with NONMEM. The induction of TT clearance caused by CP, the inhibition of CP activation by TT, and CP autoinduction involving CYP enzymes are adequately characterized with acceptable precision ($RSE\% < 17\%$) and relatively small residual variability ($RSE\% < 79\%$) utilizing this model.

15.5.4 Evaluation of Elimination Kinetics from Plasma Concentration–Time Data

Most drugs are eliminated through hepatic, renal, and/or biliary processes that may follow the first-order or M–M saturable kinetics. Typically, the one-, two-, and three-compartment models are used to describe plasma concentration–time profiles with the elimination of drugs from the central compartment as shown with models and schemes in Table 15.3. Several nontraditional and emerging compartmental elimination PK models are discussed in this chapter.

15.5.4.1 Elimination from a Compartment Other than the Central Compartment.

If either one or two elimination pathways from the central compartment and another peripheral compartment are added to the normal scheme, the elimination rate constants will be overparameterized when solving the three-compartment PK equation. In fact, it is impossible to ascertain from drug concentrations in systemic circulation whether the model should have elimination from one, two, or three compartments. Disposition of dicumarol was modeled with a three-compartment model in which elimination occurred from one of the peripheral compartment only as shown in Fig. 15.20 [19]. The transfer and elimination processes in the three-compartment open system may be represented by the following diffusion equations:

$$\frac{dA_1}{dt} = -(k_{12} + k_{13})A_1 + k_{21}A_2 + k_{31}A_3 \quad (15.44)$$

Figure 15.19 Model-predicted and individual-predicted concentrations versus the observed concentrations for thiotepa (a and b), tepa (c and d), cyclophosphamide (e and f), and 4-hydroxycyclophosphamide (g and h) [18].

$$\frac{dA_2}{dt} = -(k_{20} + k_{21})A_2 + k_{12}A_1 \quad (15.45)$$

$$\frac{dA_3}{dt} = -k_{31}A_3 + k_{13}A_1 \quad (15.46)$$

where A is the amount of drug in the designated compartment and k the rate constant.

By assuming that elimination occurred from the more rapidly accessible peripheral compartment, this model was used to describe the plasma concentration–time profile of dicumarol of the apparent first-order elimination rate constant decreased with increasing dose. This phenomenon is explained by the concentration-dependent inhibition of own biotransformation when the high concentrations of the drug are present in the liver and concentration-dependent protein binding of the drug, which was supported by the investigations with isolated perfused rat livers [20].

Figure 15.20 A three-compartment PK model for drugs that are eliminated from a peripheral compartment other than the central compartment.

Figure 15.21 Scheme of the nontraditional two-compartment open model that elimination occurs from both the central and peripheral compartments (k_{HOF} = Hofmann elimination rate constant; k_{EH} = ester hydrolysis rate constant).

15.5.4.2 Elimination from Both Central and Peripheral Compartments. When a drug is eliminated through several pathways, including both central and peripheral compartments, traditional compartmental PK models—assuming elimination from a single central compartment—are inaccurate to assess PK data. For example, the V_{ss} value of atracurium besylate, a skeletal muscle relaxant, as underestimated for $\sim 17\text{--}20\%$ [21,22] when a traditional PK model was used. The nontraditional PK model was developed to fit the plasma concentration–time data of cisatracurium besylate, a cis–trans isomerism form of atracurium besylate [23]. The scheme of the nontraditional two-compartment open model is depicted in Fig. 15.21. The model can be solved by the following equations:

$$C = Ae^{-\alpha t} + Be^{-\beta t} \quad (15.47)$$

where

$$V_1 = \frac{\text{Dose}}{(A + B)} \quad (15.48)$$

$$A = \frac{\text{Dose}(k_{20} + k_{21} - \alpha)}{V_1(\beta - \alpha)} \quad (15.49)$$

$$B = \frac{\text{Dose}(k_{20} + k_{21} - \beta)}{V_1(\alpha - \beta)} \quad (15.50)$$

$$\alpha + \beta = k_{10} + k_{12} + k_{20} + k_{21} \quad (15.51)$$

$$\alpha \times \beta = (k_{10} \times k_{20}) + (k_{10} \times k_{21}) + (k_{12} \times k_{20})$$

Input rate:

$$R_{\text{input}} = C_{\text{ss}} \times Cl_{\text{total}} \quad (15.52)$$

Elimination rate:

$$R_{\text{elimination}} = (k_{10} \times A_{1\text{ss}}) + (k_{20} \times A_{2\text{ss}}) \quad (15.53)$$

where $A_{1\text{ss}}$ and $A_{2\text{ss}}$ are the amounts drug in the central and peripheral compartments, respectively, at steady state.

This model has been successfully applied to describe the PK profile of cisatracurium besylate that is eliminated through multiple pathways, including Hofmann elimination, ester hydrolysis, and liver and renal elimination [21,24]. Results from this modeling supported the idea that the major elimination pathway of cisatracurium besylate in patients was Hofmann elimination that is spontaneous degradation in plasma and tissue at normal body pH and temperature. Approximately 77% of CL of cisatracurium besylate was accounted for by Hofmann elimination, while the residual drug (23%) was accounted for by liver and renal elimination.

15.5.4.3 Nonlinear Elimination—Michaelis–Menten and Target-Mediated Drug Disposition. Saturation may occur in all drug disposition processes where enzymes, transporters, or active processes are involved in biotransformation, renal tubular secretion, and active transport and binding. These processes may be specific with respect to the drug and may have limited capacities. For these specialized processes, the use of M–M kinetics or target-mediated drug disposition (TMDD), a specific case of M–M drug disposition, or mixed-order kinetics is usually applicable. For a drug showing M–M PK, capacity limitation of drug disposition/clearance can occur in many processes, including hepatic metabolism and renal and biliary excretion of a drug. For a drug characterized by TMDD first introduced by Levy [25], the saturable disposition/clearance is controlled by the pharmacological target, such as enzymes or receptors, of the drug. The TMDD phenomenon where the temporal profile of plasma or serum drug concentrations of a drug is significantly affected due to its high affinity binding to a biological target with a large amount of drug relative to dose. Since it is difficult to obtain clinical data for target kinetics, M–M kinetics where only free or total drug concentrations in a biological fluid are measured has been applied to the TMDD

Figure 15.22 Semilogarithmic scale concentration–time profile simulated from Michaelis–Menten model with $V_m = 0.22$, $K_m = 0.1$, and $C_0 = 1, 2$, and $4 \mu\text{g/mL}$.

Figure 15.23 Scheme of two-compartment Michaelis–Menten model.

system with less precision. M–M and TMDD models have been used to characterize large molecular weight drugs such as monoclonal antibodies and some small molecular weight drugs such as angiotensin-converting enzyme (ACE) inhibitors [26], an aldose reductase inhibitor imirestat [27], and warfarin [28].

The typical semilogarithmic concentration–time profile of a drug fitting an M–M or TMDD model (Fig. 15.22) appears to be nonlinear with a fast elimination rate at the low dose and a slow clearance rate at the high dose. Depending on the distribution and elimination rates, some drugs with the M–M characteristics may show linear PK or the combination of linear and nonlinear PK initially after administration. The structure of a two-compartment M–M model is shown in Fig. 15.23. For IV bolus injection, drug in the central compartment (C_1) is eliminated from the system by the combination of a first-order rate constant and a saturable process described by the M–M equation. The initial conditions and model equations are as follows:

Initial conditions:

$$C_1(t) = 0, \quad \text{for } t < t_D \quad (15.54)$$

$$C_2(t) = 0, \quad \text{for } t \leq t_D \quad (15.55)$$

$$C_1(t_D) = \frac{D}{V}, \quad \text{for single dose} \quad (15.56)$$

$$C_1(t_{D_1}) = C_1^{(1)}(t_{D_1}) = \frac{D_1}{V}, \quad \text{for the first dose of multiple doses} \quad (15.57)$$

$$C_1(t_{D_n}) = C_1^{(n)}(t_{D_n}) = C_1^{(n-1)} + \frac{D_n}{V}, \quad \text{for multiple doses} \quad (15.58)$$

Model equations:

$$\frac{dC_1}{dt} = -\left(\frac{V_{\max}}{K_m + C_1}\right)C_1 - (k_{12} + k_{el})C_1 + k_{21}C_2 \quad (15.59)$$

$$\frac{dC_2}{dt} = k_{21}C_1 - k_{21}C_2 \quad (15.60)$$

where C_1 and C_2 denote free drug concentrations in the central and peripheral compartments, respectively, V is the volume distribution of the central compartment, k_{12} , k_{21} , and k_{el} are the first-order rate constants, K_m is the M–M constant, and V_m is the maximum elimination rate.

For TMDD, free drug in the central compartment (C_1) binds to its free target (R) at a second-order rate constant (k_{on}), forming a drug–target complex (RC_1), which can either be internalized and degenerated at a first-order rate (k_{int}) or dissociate at a first-order rate (k_{off}). The unbound drug can also be removed from the central compartment by a first-order elimination pathway (k_{el}) and distributed to the peripheral compartment (C_2). The targets are formed with a zero-order rate constant (k_{form}) and are degenerated with a first-order rate constant (k_{deg}). The structure of the general PK model of TMDD is presented in Fig. 15.24 and the equations combined with linear and TMDD elimination and IV bolus infusion are as follows:

$$\frac{dC_1}{dt} = \ln(t) - (k_{el} + k_{12})C_1 + k_{21}C_2 - k_{on}R \cdot C_1 + k_{off}RC_1 \quad (15.61)$$

$$\frac{dC_2}{dt} = k_{21}C_1 - k_{21}C_2 \quad (15.62)$$

Figure 15.24 Scheme of two-compartment target-mediated drug disposition model.

$$\frac{dR}{dt} = k_{\text{form}} - k_{\text{deg}}R - k_{\text{on}}R \cdot C_1 + k_{\text{off}}RC_1 \quad (15.63)$$

$$\frac{dRC_1}{dt} = k_{\text{on}}R \cdot C_1 - (k_{\text{int}} + k_{\text{off}})RC_1 \quad (15.64)$$

Before applying the TMDD model to a specific drug, one should understand the underlying biological processes of drug binding to the target(s). The model discussed above can only be applied to the simple and specific drug–target binding process of one drug molecule to one target molecule. The drug–target binding occurs only in the central but not in the peripheral compartment. Free target formation and degeneration rates are independent of the drug and unbound target concentrations. Unbound drug distributes to peripheral compartment linearly. After internalizing, the bound drug will release from the drug–target complex so that the targets become free again. Recycling of the free target is not included in the elimination process of the drug–target complex. If a drug–target complex disposition deviates from the processes discussed here, the TMDD model should be modified so that an appropriate model can be used to characterize the PK of the drug.

Drug-binding microconstants (k_{on} and k_{off}) included in the TMDD model are sometimes difficult to estimate from routine clinical studies due to the much larger timescale of the concentration measurements than the timescale of the binding process unless there are extensive data in the transition phase. In this situation, the full TMDD model becomes overparameterized and the fit of the model to the available data becomes unstable. Approximations of the TMDD disposition model such as quasi-equilibrium (QE) [29], quasi-steady-state (QSS) [30], and M–M [29] approximations were further studied by several researchers to help solve the full TMDD model with certain conditions.

When the binding of drug to free receptor and dissociation of the drug–receptor complex are of several orders of magnitude faster than the other drug distribution and elimination processes, equilibrium between the binding and dissociation is reached instantly with unidentifiable k_{on} and k_{off} . As a consequence, QE approximation is suggested based on the following assumption [29]:

$$k_{\text{on}}R \cdot C_1 = k_{\text{off}}RC_1 \quad (15.65)$$

$$\frac{R \cdot C_1}{RC_1} = \frac{k_{\text{off}}}{k_{\text{on}}} \equiv K_D \quad (15.66)$$

where K_D represents the equilibrium dissociation constant. With this additional equation to the four full TMDD equations, four unknowns in the TMDD model will be easily resolved. Furthermore, the free drug and target concentrations in the central compartment are shown as follows:

$$C_1 = \frac{1}{2} \left[(C_{\text{tot}} - R_{\text{tot}} - K_D) + \sqrt{(C_{\text{tot}} - R_{\text{tot}} - K_D)^2 + 4K_D C_{\text{tot}}} \right] \quad (15.67)$$

$$RC_1 = \frac{R_{\text{tot}}C_1}{K_D + C} \quad (15.68)$$

In which, the total concentrations of the drug and target are as follows:

$$C_{\text{tot}} = C + RC_1 \quad (15.69)$$

$$R_{\text{tot}} = R + RC_1 \quad (15.70)$$

When the binding of drug to free receptor and dissociation of the drug–receptor complex are not much faster than drug elimination process, the rate of elimination of the complex is not negligible compared to the dissociation rate. In this case, QE approximation may not be valid. In this case, the QSS assumption that the binding rate is balanced by the sum of the dissociation and internalization rate can be applied to drug–target disposition [29]:

$$k_{\text{on}} R \cdot C_1 = (k_{\text{int}} + k_{\text{off}}) RC_1 \quad (15.71)$$

$$\frac{R \cdot C_1}{RC_1} = \frac{k_{\text{int}} + k_{\text{off}}}{k_{\text{on}}} = K_D + \frac{k_{\text{int}}}{k_{\text{on}}} = K_{\text{SS}} \quad (15.72)$$

$$C_1 = \frac{1}{2} \left[(C_{\text{tot}} - R_{\text{tot}} - K_{\text{SS}}) + \sqrt{(C_{\text{tot}} - R_{\text{tot}} - K_{\text{SS}})^2 + 4K_{\text{SS}}C_{\text{tot}}} \right] \quad (15.73)$$

$$RC_1 = \frac{R_{\text{tot}}C_1}{K_{\text{SS}} + C} \quad (15.74)$$

where K_{SS} denotes the steady-state constant. The QSS approximation can be applied to the drug with fast drug–target association and dissociation as well as fast internalization of the drug–target complex.

When the free drug concentration is large relative to the total target concentration, the time derivatives of the free and total drug concentrations are similar where M–M approximation can be used to solve the full TMDD model [29]. Both M–M and TMDD models are applied to the elimination process with capacity limitation and both systems are saturated at high dose. However, the M–M model exhibits linear parallel clearance at low doses. On the other hand, a very rapid drop and long terminal phase occur in TMDD systems [31]. The rapid decrease in drug concentrations reflects the loss of drug in the central compartment by rapid binding to the targets at low doses. The processes of drug elimination controlled by the rates of k_{12} , k_{21} , K_D , k_{el} , and k_{int} as well as the initial free target concentration attribute to the relatively long terminal phase.

15.6 SUMMARY

The PK of unchanged drug and the pseudo-PK parameters of TRA must be estimated in human ADME studies. With multiple PK samples collected in plasma and excreta, the PK parameters that represent the extent of a drug in or clearance from the circulation system are readily determined using a noncompartment approach that can be executed quickly in routine and traditional PK data analysis without assumption on disposition of drug in the body. Mechanism- or compartment-based PK models contain specific expression to characterize, in a quantitative manner, processes on the causal path from absorption, distribution, and metabolism to elimination. Data analysis using modeling

will provide information on not only the extent of a drug in the body but also the rate of a drug transferring through different parts of the body. Pooling PK data from a human ADME together with the data from the other studies of the same molecule can help scientists build a more robust population PK model, which can be used in interpreting or predicting the underlying physiological or pathological processes that drugs act on and for optimizing therapy with drugs that have a complex disposition.

16.1 SUMMARY

Physiologically based pharmacokinetic (PBPK) models are increasingly being used to describe and define more meaningful parameters that relate to physiology, anatomy, and biochemistry in the prediction of pharmacokinetic (PK) profiles and tissue concentration–time profiles of the parent drug and metabolites and to provide mechanistic insight in drug dynamics. Physiological data (blood flow rates and tissue volumes), physical data (protein binding and tissue partition coefficients), and biochemical data (Michaelis–Menten parameters for transporters and enzymes, $V_{\max}/K_m$) are the information required for building a PBPK model. Recently, single organ PBPK models for the intestine, liver, and kidney were applied to examine the influences of blood flow, protein binding, and activities of transporters and enzymes on the area under the curves (AUCs) and clearances of a drug and its formed metabolite. These in turn are used to build whole-body PBPK models consisting of the major drug elimination organs (i.e., intestine, liver, and kidney), together with

highly perfused, poorly perfused, and adipose tissues. The whole-body PBPK model approach is extremely useful to understand sequential metabolism, the kinetics of metabolites, and examine effects of the transporter and enzyme interplay on the blood and target organ exposures of the drug and its metabolites. The application of PBPK models allows one to make predictions of the exposure in target sites, pharmacological activity, or toxicity and the effects of age, pregnancy, disease states, and drug–drug interactions (DDIs). In this chapter, cases for the application and usefulness of PBPK models are summarized.

16.2 INTRODUCTION

PK models represent mathematical descriptions that relate drug concentration levels to processes of drug absorption, distribution, metabolism, and excretion (ADME) *in vivo*. Various modeling approaches have been developed with varying degrees of complexity for applications in different situations. A popular approach is the classic PK compartmental modeling approach which describes the body as rapidly and/or poorly equilibrating compartments for the distribution of drugs/chemicals [1]. These models are the simplest and therefore the most widely used in the clinical setting to provide information on the extents of drug distribution and elimination. The major disadvantage of these models is that the plasma drug concentrations do not always reflect tissue drug concentrations that relate to drug responses and toxicological effects. Moreover, these approaches show serious limitations since the physiological processes, especially transporter function and the sequential handling of metabolites within metabolite formation organs, are not well described [2]. These limitations pave the way to the development of PBPK approaches.

PBPK models are increasingly being used to describe and define more meaningful parameters that relate to physiology, anatomy, and biochemistry. The approach is based on the assumption that compartments are homogeneous and well-stirred. The earliest description of PBPK models was introduced in the 1930s by Teorell, one of the pioneers of PK who applied mass balance equations on specific tissues and related to tissue volumes and organ perfusion rates on drug absorption, distribution, and elimination [3]. The elegant works of Bischoff and Dedrick during the 1950s–1970s then firmly established the importance of PBPK models in the prediction of drug protein binding, tissue distribution, and the disposition of thiopental and anticancer drugs in animals [4–6]. The usefulness of these models was evident, since animal data, when scaled up, were able to predict the concentration–time profiles in man [7,8]. The concepts are then used toward the description of eliminating organs [9–14].

The PBPK model consists of a number of subcompartments that represent actual tissues and organs of discrete volumes. The differential equations constructed for these models are based on three different classifications of parameters: physiological, thermodynamic/physical, and biochemical. Physiological parameters include tissue volumes (V) and tissue blood flow rates (Q) whose sum provides the cardiac output (Q_{CO}). One basic premise of PBPK models lies with the assumption that there is venous equilibration: the concentration in tissue blood equals that in the emergent blood. Thermodynamic parameters include protein binding (denoted as unbound fractions in plasma, blood, or tissue: f_P , f_B , or f_u , or f_T), the tissue to plasma/blood partition coefficient ($K_{P,T}$ or $K_{P,Tu}$) of the drug, and the transmembrane permeability. Biochemical

parameters exist as the result of metabolic and transport processes and are described by the constants, the $V_{\max}$ or maximum velocity and K_m , the Michaelis–Menten constant. The rate is given by the product of the substrate concentration $[S]$ and the intrinsic clearance, CL_{int} . Under first-order conditions, the CL_{int} is given by $V_{\max}/K_m$. The secretory intrinsic clearance ($CL_{\text{int,sec}}$) is responsible for renal, biliary, or luminal excretion. For transport, the influx (CL_{in}) and efflux (CL_{ef}) clearances are included to represent both the transporter-mediated and passive diffusion processes [15–18].

The prediction of PK profiles of new chemical entities in humans, based on *in vitro* and *in vivo* preclinical data, is an extremely useful technique that provides important information in the drug discovery and development phases to identify drug candidates with desirable, PK properties. These many useful features that appear in PBPK models are particularly pertinent in drug development [19–22] and health risk assessment [23–29]. Another feature rests on the scale-up of PBPK based on animal experiments (mouse, rat, dog, or monkey) to explain drug behaviors in humans [7,8,30–34]. Moreover, PBPK models have been routinely applied to predict tissue concentrations with respect to the route and dose of drug administration, and in the appraisal of how alteration of physiological or biochemical conditions such as in disease states [35–38] or genetic variants in transporters, enzymes, and/or protein binding would affect drug disposition [39,40].

Another area of development rests on single-organ PBPK models such as the intestine, liver, or kidney which furnish mathematical solutions comprising blood flow, protein binding, and transporter and enzymatic activity parameters for the AUC [15,16,18]. The relations among these parameters allow the examination of important determinants on organ clearances, the interplay between transporters and enzymes, and mechanisms of DDI within these frameworks [15,16,18]. These solutions pertain to the single organs and are readily used to compare the kinetics between formed and preformed metabolite.

In this chapter, we review the information needed for building a PBPK model and the general approaches used. We summarize the recently developed single-organ PBPK models for the intestine, liver, and kidney and whole-body PBPK models that are currently applied to gain a mechanistic understanding in drug disposition. The models can predict drug and metabolite concentrations in tissues at any time and provide mechanistic insight in drug dynamics. Currently, model predictions of lipophilic compounds surpass those which require transporter involvement for uptake and efflux or those that exhibit diffusion-limited transport. These PBPK models established for animals may be scaled up to man on the extrapolation of *in vitro* experimental findings to *in vivo* PK parameters.

16.3 BASIC CONSIDERATIONS

A general PBPK model is depicted in Fig. 16.1. The model consists of several tissue compartments that represent anatomic tissue regions in the body where the drug is distributed or metabolized/excreted. Enterohepatic circulation and renal reabsorption, processes that prolong the duration of drug and metabolite in the body, are readily incorporated. Although there is no general rule for the type of organ compartments to be included in the model, organs in which the drug exerts a pharmacologic and/or toxic response should be included. In principle, if all parameters that affect the disposition

Figure 16.1 A physiologically based pharmacokinetic (PBPK) model of the whole body. Physiological volume (V), blood flow rate (Q), drug concentration (C), and tissue partition coefficient ($K_{p,T}$) in the brain (“brain”), heart (“heart”), lung (“lung”), liver (“L”), kidney (“K”), intestine (“I”), adipose tissue (“fat”), and other tissue (“other”) are some of the needed parameters for modeling; the blood is represented as (“B”). FR is the fraction reabsorbed in the kidney, and GFR is the glomerular filtration rate.

of the drug are known *in vitro*, the model should be able to predict the PK of the drug *in vivo*. However, because of the complexities and differences inherent in the systems, many assumptions are needed to render a sound *in vitro*–*in vivo* extrapolation (IVIVE) before forming the proper mathematical relations to describe drug concentrations in the blood and tissues and physiological processes on transport, secretion, and metabolism within tissue compartments.

16.3.1 Physiological Data: Blood Flow Rates and Tissue Volumes

Blood flow rates and physiological tissue volumes are important parameters of PBPK models. Table 16.1 summarizes these flow parameters that show differences among

TABLE 16.1 Physiological Volumes and Blood Flow Rates in the Human, Rat, and Mouse^a

Tissue	Human (70 kg)		Rat (0.25 kg)		Mouse (~0.02 kg)

species. Blood flow is an important determinant in drug clearance in PBPK modeling. Although the pattern of blood flow, such as bulk flow, plug flow, or dispersive flow, into organs, such as the liver, affects the degree of mixing in the organ and transport and metabolic activities [10,41,42], bulk flow is usually considered. It is noteworthy that the blood flow rate to a specific organ may not reach the tissue site in its entirety. For example, part of the kidney plasma is filtered by glomerular filtration, and only the difference between the plasma flow and the GFR reaches the postglomerular tubular cells [11,12]. In the intestine, the blood flow reaching the enterocytes housing absorptive and secretory apical transporters and enzymes represents a small proportion of the entire intestinal blood flow [14].

16.3.2 Physical Data

16.3.2.1 Plasma Protein Binding. The binding of drugs to plasma protein usually retards the elimination of drugs. The pharmacological activity and toxicity of drugs are generally assumed to be correlated to the unbound drug concentration in the blood or tissue, and only the unbound drug is the species that is metabolized or excreted. Depending on whether the drug is a weak or strong acid or base, or is a neutral compound or zwitterion, it may bind to a single protein or multiple proteins (e.g., serum albumin, α_1 -acid-glycoprotein, or lipoproteins) in blood [10,45]. For poorly extracted drugs, increasing the extent of binding to plasma proteins would decrease the rate of excretion in the kidney and the rate of metabolism in the liver [46,47], but binding exerts less influence on highly extracted drugs, whose elimination rates are more dependent on the blood flow [10,48]. Changes in plasma protein binding from disease states or DDIs may lead to clinical outcomes that require the adjustment of

dosage regimens. Therefore, drug binding to plasma proteins is a key determinant of clearance.

The binding of a drug to plasma proteins is usually a reversible process, denoted by the on (k_{on}) and off (k_{off}) rate constants. The ratio of these constants yields the binding association constant, K_A , and a value of less than $10^4/\text{M}$ suggests poor binding, whereas the one exceeding $10^4/\text{M}$ suggests tighter binding [49]. For the latter case, dramatic changes in the extent of protein binding are evoked on small changes in drug concentration when the binding association constant is high. The unbound plasma concentration, $C_{P,u}$, in plasma can be expressed as follows:

$$C_{P,u} = \frac{-(1 + nK_A P_t - K_A C_P) + \sqrt{(1 + nK_A P_t - K_A C_P)^2 + 4K_A C_P}}{2K_A} \quad (16.1)$$

where P_t is the protein concentration and n represents the number of binding sites within the same class of site. The bound plasma concentration ($C_{P,b}$) is expressed as the difference between the total (C_P) and unbound ($C_{P,u}$) plasma concentrations.

If the binding between a drug and plasma protein involves two classes of sites, one with low affinity and the other with higher affinity, such a binding involving two noncooperative affinities may be formulated as [50]

$$\frac{C_{P,b}}{C_{P,u}} = \frac{n_1 K_{A1} P_t}{1 + K_{A1} C_{P,u}} + \frac{n_2 K_{A2} P_t}{1 + K_{A2} C_{P,u}} \quad (16.2)$$

where K_{A1} and K_{A2} are the binding constants for class I and class II and n_1 and n_2 are the corresponding number of noncompetitive binding sites on the protein molecule. At low drug concentration, protein binding is not saturated and only the high affinity site is involved in the binding. When excess drug is present, the low affinity sites will be further recruited for binding. In such a case, the unbound fraction $C_{P,u}$ is a function of the binding to both the high and low affinity binding sites.

16.3.2.2 Tissue Partition Coefficient. The tissue partition coefficients are important drug-specific input parameters in PBPK modeling. The tissue–plasma (or plasma water) partition coefficient, $K_{P,T}$ (or $K_{P,Tu}$), is defined as the tissue (C_T) to the tissue plasma ($C_{T,P}$) (or plasma water ($C_{T,Pu}$) concentration ratio of the drug. Since the drug concentration in tissue plasma, total or unbound ($C_{T,P}$ or $C_{T,Pu}$), equals that leaving the tissue ($C_{T,P,out}$ or $C_{T,Pu,out}$), the following relations hold at steady state [9,51,52]:

$$K_{P,T} = \frac{C_{T,ss}}{C_{P,ss}} \text{ or } K_{P,Tu} = \frac{C_{T,ss}}{C_{Pu,ss}} \quad (16.3)$$

One may also express this ratio relative to the blood concentration.

The partition coefficient, when multiplied to the volume of the tissue, determines the effective volume of distribution of drug in the tissue ($V_{T,app}$). The sum of all the tissue volumes eventually provides the V_{ss} , or the steady-state volume of distribution, a commonly used parameter to denote the extent of drug distribution, as a plasma or blood equivalent volume [53].

There are several *in vitro* methods to determine $K_{P,T}$ within tissues, some of which are quite time consuming [54–56]. In addition, *in vivo* approaches exist for estimating

$K_{P,T}$ from blood and tissue after constant rate infusion or injection to animals [57–59]. These experimentally determined constants would underestimate the true $K_{P,T}$ (ratio of influx/efflux rate constants or influx/efflux intrinsic clearances) when elimination exists within the organ or tissue, since the denominator of Equation 16.3 is artificially increased due to the presence of the elimination rate constant or elimination intrinsic clearance [60].

Recent approaches have been developed for the prediction of $K_{P,T}$ [58,61,62]. These approaches require some understanding of the physiochemical properties of the drug as well as distribution mechanisms or binding to tissue neutral lipids, phospholipids, and intracellular water. However, most of the models are suitable for small neutral molecules only and will result in significant inaccuracies when applied to compounds that are extensively ionized at physiological pH. To solve this problem, Rodgers and Rowland [63] incorporated drug ionization in both intra- and extracellular water into the approaches developed by Poulin *et al.* [62]. Under physiological condition, basic drugs ($pK_a \geq 7$) such as β -blockers are sufficiently ionized; their electrostatic interaction with acidic phospholipids predominates and accounts for the tissue binding (Eq. 16.4) [63,64]. For acids, very weak bases, neutrals, and zwitterions, their binding to extracellular proteins contributes to the binding and the electrostatic force towards acidic phospholipids is minimal (Eq. 16.5) [63,65].

For basic compounds, K_{pu} is

$$K_{pu} = \left[\left(\frac{1 + X \cdot f_{IW}}{1 + Y} \right) + f_{EW} + \left(\frac{K_{A,AP}[AP]_T \cdot X}{1 + Y} \right) + \left(\frac{P \cdot f_{NL} + (0.3P + 0.7)f_{NP}}{1 + Y} \right) \right] \quad (16.4)$$

For acids, very weak bases, neutrals, and zwitterions, K_{pu} is

$$K_{pu} = \left[\left(\frac{1 + X \cdot f_{IW}}{1 + Y} \right) + f_{EW} + (K_{A,PR}[PR]_T) + \left(\frac{P \cdot f_{NL} + (0.3P + 0.7)f_{NP}}{1 + Y} \right) \right] \quad (16.5)$$

where P is the octanol:water partition coefficient or concentration ratio of the unionized compound in all tissues except the adipose tissue, whose partition coefficient is assessed as the vegetable or olive oil:water partition coefficient or concentration ratio; f is the fractional tissue volume; subscripts IW and EW represent the intracellular and extracellular tissue water, respectively; NP and NL denote the neutral phospholipids and neutral lipids, respectively; $[AP]_T$ is the tissue concentration of acidic phospholipids; and $[PR]_T$ is concentration of extracellular albumin (for acid and weak base) or lipoprotein (for neutral compounds). The terms, X , Y , and Z , are terms that account for the extents of drug ionization as defined in Table 16.2.

$K_{A,AP}$ in Equation 16.4 is the binding association constant for the interaction between basic drugs to acidic phospholipids, and $K_{A,PR}$ in Equation 16.5 is the binding association constant for the interaction between acidic or neutral compounds, weak bases, or zwitterions and extracellular albumin/lipoprotein. For weak bases, the binding association constant in red blood cells (RBCs), $K_{A,RBC}$, may be estimated using

TABLE 16.2 Definition of the Terms X , Y , and Z in Equations 16.4–16.8

	X	Y	Z
Monoprotic base	$10^{pK_a - pH_{IW}}$	$10^{pK_a - pH_p}$	$10^{pK_a - pH_{BC}}$

Monoprotic acid	$10^{pH_{IW} - pK_a}$	$10^{pH_p - pK_a}$	NA
Diprotic acid ^a	$10^{pH_{IW} - pK_{a1}} + 10^{2pH_{IW} - pK_{a1} - pK_{a2}}$	$10^{pH_p - pK_{a1}} + 10^{2pH_p - pK_{a1} - pK_{a2}}$	NA
Zwitterion	$10^{pK_{a,BASE} - pH_{IW}} + 10^{pH_{IW} - pK_{a,ACID}}$	$10^{pK_{a,BASE} - pH_p} + 10^{pH_p - pK_{a,ACID}}$	$10^{pK_{a,BASE} - pH_{BC}} + 10^{pH_{BC} - pK_{a,ACID}}$
Neutral	0	0	NA

^aIn these expressions $pK_{a1} < pK_{a2}$; pH_p is the pH of plasma

Abbreviation: NA, not available.

Equation 16.6 with the known unbound fractions ($f_{IW,RBC}$, $f_{NL,RBC}$, and $f_{NP,RBC}$), the X , Y , and Z terms from Table 16.2, and $K_{Pu,RBC}$ from Equation 16.7; the $K_{A,RBC}$ so estimated is assumed to equal $K_{A,AP}$, which, in turn, may be applied to estimate K_{pu} in Equation 16.4:

$$K_{A,RBC} = \left[K_{Pu,RBC} - \left(\frac{1+Z}{1+Y} f_{IW,RBC} \right) - \left(\frac{P \cdot f_{NL,RBC} + (0.3P + 0.7)f_{NP,RBC}}{1+Y} \right) \right] \left(\frac{1+Y}{Z[AP]_{RBC}} \right) \quad (16.6)$$

$$K_{Pu,RBC} = \frac{Hct - 1 + \left(\frac{C_B}{C_P} \right)}{f_P Hct} \quad (16.7)$$

Specifically, $K_{Pu,RBC}$ is the ratio of drug concentration in RBCs to that unbound in plasma and represents the binding association constant of drug molecules to RBCs. C_B/C_P is the blood:plasma concentration ratio and Hct is the hematocrit; f_P is the fraction of drug unbound in plasma; and subscripts RBC and P denote the red blood cells and plasma, respectively.

For acidic, neutral, and weakly basic compounds or zwitterions, the binding association constant $K_{A,PR}$ is given by the following equation:

$$K_{A,PR} = \left[\frac{1}{f_P} - 1 - \left(\frac{P f_{NL,P} + (0.3P + 0.7)f_{NP,P}}{1+Y} \right) \right] \left(\frac{1}{[PR]_P} \right) \quad (16.8)$$

After obtaining the K_{Pu} values, the V_{ss} is calculated as

$$V_{ss} = V_P + f_P \sum V_{T,i} K_{Pu,T,i} \quad (16.9)$$

where V_P is the volume of plasma and $V_{T,i}$ is the volume of the i th tissue/organ; the term $V_{T,i} K_{Pu,T,i}$ is $V_{T,app}$ or the apparent volume of the tissue compartment for the i th tissue/organ [63]. Equation 16.9 is a general approach to estimate the steady-state volume of distribution, V_{ss} .

However, PBPK models are very complex and the number of organ/tissue compartments can exceed 15 or more [19,66]. A strategy for simplification is to lump the compartments and reduce the complexity of the PBPK model without losing the predictive power. The underlying strategies are as follows: (i) tissues with same model specification for flow or partition (e.g., both are highly/poorly perfused or of similar K_p) and of same position in the system structure can be lumped together; (ii) serial tissues that equilibrate with one another rapidly should be lumped; and (iii) parallel tissues that have similar rate constants may be lumped [19]. It was suggested that the preliminary estimation of V_{ss} can be based solely on $K_{P,muscle}$ and $K_{P,fat}$ [59,61,63] since drug distribution into muscle and fat accounts for approximately 65–84% of the total V_{ss} ; the $K_{P,muscle}$ may be used for all lean tissues except for the lungs which are represented by the $K_{P,fat}$ [59]. This new idea provides a time-efficient prediction of $K_{P,T}$ for lumped compartments in developing the PBPK models.

16.3.3 Biochemical Data on Enzymes and Transporters

The basic tissue compartment usually represents an individual organ or a group of “lumped” organs/tissues with similar flow parameter or partition characteristics. After giving consideration to the above general concepts, there is the need to consider transporters and enzymes (see Chapters 5–7) as important biochemical parameters in building a PBPK model. Rate equations may then be used to describe the transport and enzymatic processes. For the description of rate processes, the simplest Michaelis–Menten equation is often used, wherein the rate, v , is expressed in terms of the intrinsic clearance for transport, metabolism, and/or secretion (CL_{in} , CL_{ef} , $CL_{int,met}$, or $CL_{int,sec}$):

$$v = \frac{V_{max}}{K_m + [S]}[S] = CL_{int}[S] \quad (16.10)$$

The intrinsic clearance for a particular process is the maximum velocity, V_{max} , divided by the sum of the Michaelis–Menten constant, K_m , and the unbound substrate concentration, $[S]$ or $V_{max}/(K_m + [S])$. For this reason, the binding of the drug to microsomes/cytosol must be examined to better define $[S]$ [67–69]. The V_{max} and K_m values are usually obtained from *in vitro* studies, commonly estimated from the rate plot (v vs $[S]$), the Lineweaver–Burk, Eadie–Hofstee, or Hanes–Wolf plot. Usually, the assumption is that elimination is first order, and CL_{int} is the ratio of V_{max}/K_m . The *in vitro* intrinsic metabolic clearance under linear conditions is given by [70]

$$CL_{int,met,in\ vitro} = \frac{V_{max}}{K_m} \quad (16.11)$$

Metabolic or enzyme functions, estimated from human liver microsomal and cytosolic incubations, supersomes or recombinant expression systems, and the appropriate scaling factors, are converted to per gram liver when the hepatocellularity (cells per gram liver), microsomal protein (mg/g liver), and the overall expression of the cytochrome P450 (CYP) enzyme (pmol/g liver) are involved in converting the *in vitro* data to provide the $CL_{int,met}$ in human liver *in vivo* [43,71–73]. Preference of recombinant systems over human liver microsomes (HLMs) has been expressed, offering improved assay sensitivity compared with HLM for $CL_{int,met}$ determination [74].

The transporter-mediated processes and passive diffusion into and out of the tissue compartment must be summed to yield the influx (CL_{in}) and efflux (CL_{ef}) clearances, respectively. Normally, transporter function may be estimated in cell expression systems, combined with human transporter uptake studies. The influx transport intrinsic clearance (CL_{in}) is usually estimated from *in vitro* hepatic uptake studies. However, quantitative data on how much protein of each of the transporters is expressed within different tissue region is lacking to accurately define the relative proportions or abundancy of sinusoidal transporters for uptake and apical transporters for excretion. Moreover, the localization of the transporter, whether within the cytosol or nucleus or on the membrane surface would greatly affect the transport rate. In order to gain this insight, use of proteomics, with LC-MS/MS technologies to provide the absolute quantification of transporters, must be completed to provide the relative proportions of transporters in the liver, kidney, and blood–brain barrier [75,76]. In absence of these data, hepatocyte uptake information for extrapolation of *in vitro* parameters to *in vivo*,

cell number per unit tissue weight and tissue weight per unit body weight, in addition to the physiological scaling factors, have been used [39,77–79]. At a qualitative level, *in vitro* uptake and biliary excretion data using the rat and human sandwich-cultured hepatocyte systems may be used to assess whether there is species similarity and correlation to the *in vivo* plasma and biliary clearances [80] or DDI in transport; care must be included to describe differences in transporter expression in the system as well as real species differences. Indeed, *in vitro* data have identified marked species differences for the MRPs (multidrug resistance-associated proteins) and BCRP (breast cancer resistance protein) in rat and human hepatocytes; these significant species differences in efflux transporter activities could be integrated into animal data for the prediction of human transport [81]. When there is no significant interspecies difference between rat and man, the scaling factor determined in rats has been used to extrapolate human *in vitro* parameters to those *in vivo*. The transporter-mediated transport clearance should then be considered, in addition to the passive clearance, for the prediction of *in vivo* intrinsic influx and efflux clearances.

16.4 TYPES OF MODELS

Two tissue type models are considered: the membrane-limited model and blood flow-limited model (Fig. 16.2a and b). These PBPK models are also extended to describe the sequential metabolism or the excretion of formed metabolites (Fig. 16.2c). In any one PBPK model, a mixture of these may be used. The membrane-limited subcompartment is used for poorly permeable tissues, whereas for other tissue sites that rapidly equilibrate with blood, the flow-limited compartment may be used.

16.4.1 Membrane-Limited Model

Each tissue compartment basically consists of three well-mixed subcompartments: a vascular space that houses the blood that is perfusing the tissue, an interstitial space, and a cellular space (Fig. 16.2a). The drug enters with the afferent tissue blood flow (Q_T) with arterial concentration (C_A) into the vascular subcompartment, where there is instantaneous equilibrium with drug in the interstitium (C_{TI}). For all intents and purposes, the interstitial space may be combined with the vascular space to yield the extracellular compartment representing the tissue blood subcompartment of concentration, C_{TB} . With venous equilibration, C_{TB} equals the efferent blood concentration ($C_{T,out}$). The rate equations and the clearance terms used to describe the transport and enzymatic processes are the intrinsic clearances (CL_{in} and CL_{ef}) for influx and efflux at the basolateral membrane, respectively, and $CL_{int,sec}$ and $CL_{int,met}$ for excretion at the apical membrane and metabolism within the tissue.

Within the tissue compartment, the drug may become bound to tissue proteins, metabolized by enzymes with metabolic intrinsic clearance, $CL_{int,met}$, or is effluxed out of the cell by transporters and/or passive diffusion (CL_{ef}), or excreted at the apical membrane ($CL_{int,sec}$). The rate equations for the tissue blood (TB) and tissue (T) compartments are

$$V_{TB} \frac{dC_{TB}}{dt} = Q_T C_A - Q_T C_{T,out} + f_T C_T CL_{ef} - f_B C_{TB} CL_{in} \quad (16.12)$$

$$V_T \frac{dC_T}{dt} = f_B C_{TB} CL_{in} - f_T C_T (CL_{ef} + CL_{int}) \quad (16.13)$$

Figure 16.2 Typical PBPK components within an organ. There are two types of tissue models: (a) membrane limited; (b) blood flow limited; and (c) sequential metabolism of the formed primary metabolite (Mi) from parent drug (P) to the secondary metabolite (Mii) may occur within the organ of formation.

where f_B and f_T are the unbound fractions in blood and tissue, respectively, and CL_{int} is the total intrinsic clearance (sum of $CL_{int,met}$ and $CL_{int,sec}$).

16.4.2 Flow-Limited Model

The above relations are simplified with the assumption that the transfer across the membrane is rapid compared to the perfusion rate of the tissue (CL_{in} and $CL_{ef} \gg Q_T$). This means that the vascular, interstitial, and cellular subcompartments are in rapid equilibrium. As a result, these three subcompartments are combined to form one tissue compartment (Fig. 16.2b). The tissue to blood/plasma concentration ratio ($K_{P,T}$ or $C_T/C_{T,out}$) is used in this simplification. The mass balance equation can be written as

$$V_T \frac{dC_T}{dt} = Q_T C_A - Q_T C_{T,out} - f_T C_T CL_{int} = Q_T C_A - Q_T \frac{C_T}{K_{P,T}} - f_T C_T CL_{int} \quad (16.14)$$

where $C_T/K_{P,T}$ replaces $C_{T,out}$.

16.4.3 Model for Sequential Metabolism

The membrane-limited and flow-limited PBPK models are readily extended to describe the formation and sequential handling of the metabolite [82]. The PBPK model serves to describe sequential metabolism very well [15,82], especially when the nascently formed metabolite is immediately metabolized or excreted [83–85]. The rate equations for the tissue blood (TB) and tissue (T) compartments are expressed in Equations 16.15 and 16.16. Note that the set of parameters pertaining to the metabolite are qualified by {mi} for the concentrations, the binding constants, and the transport intrinsic clearances:

$$V_{TB} \frac{dC_{TB}\{mi\}}{dt} = Q_T C_A\{mi\} - Q_T C_{T,out}\{mi\} + f_T\{mi\} C_T\{mi\} CL_{ef}\{mi\} - f_B\{mi\} C_{TB}\{mi\} CL_{in}\{mi\} \quad (16.15)$$

Within the metabolite formation organ, the metabolite is immediately removed by intrinsic clearance, $CL_{int,met}\{mi\}$, and PBPK modeling considers the sequential handling of the formed metabolite [2]:

$$V_T \frac{dC_T\{mi\}}{dt} = f_T C_T CL_{int,met} + f_B\{mi\} C_{TB}\{mi\} CL_{in}\{mi\} - f_T C_T\{mi\} (CL_{ef}\{mi\} + CL_{int,met}\{mi\}) \quad (16.16)$$

PBPK metabolite modeling allows one to compare the kinetics between the formed versus preformed metabolite and brings a new perspective to differences in the kinetics of formed versus preformed metabolite. This is an interesting aspect for safety considerations of metabolites, if the information on the kinetics of the formed metabolite is predicted/gained on administration of a preformed metabolite, as in metabolite-in-safety testing (MIST) [15,86]. Use of the PBPK model will provide more accurate predictions on the kinetics of sequential metabolism for the investigation of risk assessment and toxicity associated with drug metabolite. However, there is a divergence for metabolite handling when metabolites display poor permeability across biological membranes [83,87,88]. The membrane barrier bars the metabolite from entering or leaving the tissue, thereby rendering differences in fates of the formed versus preformed metabolite kinetics.

16.5 PBPK MODELS OF ORGANS

The development of PBPK models, especially on simple organs for drugs and metabolites, has provided solutions for the AUCs and clearances for a drug and its formed metabolite. Rate equations are written for each subcompartment, providing the essential coefficients for matrix inversion and solutions which yield the steady-state concentrations/AUCs of the drug and of the metabolite ($AUC\{mi, P\}$) [15]. The method of matrix inversion, appropriate only under linear kinetic conditions, has been applied to examine whether $AUC\{mi, P\}$ is suitable for estimation of the systemic bioavailability [18].

16.5.1 The Liver

A liver PBPK model that describes membrane-limited transport, with either fast or slow transmembrane transport clearances for summed diffusion-limited and transporter-mediated transport cases, denoted as CL_{in} and CL_{ef} , has been developed [89,90]. The model comprises of four compartments: the reservoir (R, or blood compartment), liver blood (LB), liver tissue (L), and bile compartment (bile) (Fig. 16.3) [15]. The hepatic flow rate and unbound fraction in blood and liver are denoted by Q_H , f_B , and f_L , respectively. The transport processes underlying carrier-mediation and passive diffusion are denoted by the influx and efflux intrinsic clearances (CL_{in}^H and CL_{ef}^H) representing the summed activities of basolateral transporters and passive diffusion (Fig. 16.3). In addition, biliary secretion at the apical membrane and metabolism within hepatocytes are denoted by the biliary intrinsic clearance ($CL_{int,sec,H}$) and metabolic intrinsic clearance ($CL_{int,met,H}$) of phase I and phase II enzymes, respectively (Fig. 16.3). The model also serves to describe hepatic sequential metabolism [2,15,82,84], in which the metabolite formed within the liver tissue is prone to sequential metabolism immediately to form other metabolites ($CL_{int,met,H\{mi\}}$) or is immediately excreted ($CL_{int,sec,H\{mi\}}$).

An advantage of PBPK model is that solutions relating to blood flow, protein binding, and activities of the transporters and enzymes for the elimination of the drug and metabolite may be derived by matrix inversion from the rate equations for the drug and metabolite [15,18,91]. Pang *et al.* [15] had summarized the AUC from time 0 to ∞ for the drug and the metabolite for the liver PBPK model. As shown in Table 16.3, the AUC of the drug is a complex equation that relates to the flow rate (Q_H), f_B , CL_{in}^H , and CL_{ef}^H , and the total hepatic intrinsic clearance ($CL_{int,H}$). In the case of a drug of

Figure 16.3 Physiologically based pharmacokinetic (PBPK) liver model, with liver as the only elimination organ. See text for description of the model.

flow-limited distribution (i.e., when $CL_{in}^H \cong CL_{ef}^H > Q_H$), these equations are simplified (Table 16.3). The ratio of hepatic metabolic and biliary clearances, $CL_{H,met}/CL_{H,sec}$ equals the ratio of the intrinsic clearances, $CL_{int,met,H}/CL_{int,sec,H}$. From this relation, the unknown parameter, $CL_{int,sec}$ may be obtained with the data from liver perfusion studies or *in vivo* studies [92] when $CL_{int,met}$ is obtained from *in vitro* metabolism studies using 9000g supernatant fractions or liver microsomes. These equations shown in Table 16.3 are useful to allow inferences on mechanisms of DDIs in the liver to be made.

The AUC for the formed metabolite, $AUC_{iv}\{mi,P\}$, after iv dosing of the precursor drug is dependent on the formation (metabolic) intrinsic clearance from the drug, $CL_{int,met1,H}$, and individual components of the $CL_{int,H}$ (or $CL_{int,met1,H} + CL_{int,met2,H} + CL_{int,sec,H}$), as well as binding, transport clearances ($CL_{in}^H\{mi\}$ and $CL_{ef}^H\{mi\}$), and intrinsic clearance, $CL_{int,H}\{mi\}$, of the metabolite [sum of ($CL_{int,met,H}\{mi\}$) and ($CL_{int,sec,H}\{mi\}$)]. In contrast, the AUC obtained from administration of its preformed counterpart that yielded $AUC_{po}\{pmi\}$ and $AUC_{iv}\{pmi\}$ is independent of drug parameters [15,86]. Indeed, solutions for the formed metabolite after oral and intravenous drug dosing ($AUC_{po}\{mi,P\}$ and $AUC_{iv}\{mi,P\}$) have revealed interesting differences from $AUC_{po}\{pmi\}$ and $AUC_{iv}\{pmi\}$ that result from the administration of the preformed counterpart [15,86].

Other aspects that contribute to differences between $AUC_{po}\{mi,P\}$ and $AUC_{iv}\{mi,P\}$ after drug dosing and $AUC_{po}\{pmi\}$ and $AUC_{iv}\{pmi\}$ after preformed metabolite dosing have been attributed to the heterogeneity of transporters and metabolic enzymes. As an improvement, zonal PBPK liver models consisting of three zonal regions: zones 1 (periportal zones), 2 (midzonal zones), and 3 (perivenous zones) or models similar to compartments in series have been developed [92–95]. Another factor is the presence of a basolateral membrane barrier for the metabolite, retarding entry or efflux of preformed metabolite into and out of cells but trapping the formed metabolite within the tissue [83,87,88,96]. Many successful examples of zonal PBPK modeling include enalapril [89,94], morphine [97], estrone sulfate [98], estradiol–17 β -glucuronide [99], and digoxin [95], which were all investigated within rat liver perfusion studies. Furthermore, the role of the efflux transporter, Mrp2, which is responsible for excretion of both the parent drug, estradiol–17 β -glucuronide and its 3-sulfate–17 β -glucuronide metabolite on net desulfation, was elucidated comprehensively within the framework of a liver PBPK model [99,100].

Digoxin, a cardiotonic agent, is an example of a poorly cleared compound whose uptake into hepatocytes is rapid due to passive diffusion and the transporter, Oatp1a4, and whose clearance may be rate-limited by binding to RBCs and albumin [95]. Moreover, for poorly cleared substrates, heterogeneity in the metabolic activities among zones fails to affect the overall clearance when the drug concentration gradient within the sinusoid is shallow [92]. Drugs that are highly extracted exhibit a steep concentration gradient in the sinusoid, and, under this instance, removal rates are greatly modulated by enzyme/transporter heterogeneity. Sequential metabolism in liver could be affected by the zonal localization of metabolic enzymes. For example, different metabolites were observed for salicylamide versus gentisamide, hydroxylated metabolite of salicylamide, administration: due to the close proximity of hydroxylation and glucuronidation enzymes in the sequential metabolism of salicylamide, gentisamide glucuronidation predominates over sulfation; in contrast, gentisamide sulfate conjugates are more abundant when gentisamide is administered [85,101,102].

TABLE 16.3 Equations on the Area Under the Curve (AUC) and Total Hepatic Clearance ($CL_{H, \text{tot}}$)

Parameters	Membrane-Limited Case	Flow-Limited Case

16.5.2 The Small Intestine: Traditional Model (TM) and Segregated Flow Model (SFM)

Drugs administered orally are first absorbed, either passively or via active/facilitated transport, across the intestinal luminal membrane to reach the systemic circulation. The various intestinal transport proteins present on the apical membrane are known to participate in the uptake of drugs. Efflux by adenosine triphosphate (ATP)-binding cassette transporters delimits drug absorption in the intestine, whereas absorptive transporters mediate drug absorption [103–105]. Additionally, the intestine possesses the conjugating enzymes, UDP-glucuronosyl transferases) and GST (glutathione S-transferases) [106,107], and CYP3A, accounting for ~80% of the total immunoquantified CYPs [108–112] that play important roles in reducing oral bioavailability. Processes of intestinal absorption, metabolism, and secretion must be considered simultaneously in viewing oral drug bioavailability, and PBPK models have been developed to describe these processes [14,104,113,114].

A traditional, physiologically based model (traditional model, TM), which regards the intestine as a single homogeneous compartment with all of the intestinal blood flow perfusing the tissue, has been developed to account for oral drug bioavailability (Fig. 16.4a) [13]. This model encompasses all the variables of transport, metabolism, efflux, gastrointestinal transit, and absorption. In this model, the intestine is composed of three subcompartments: intestinal blood, tissue, and lumen. The blood or reservoir (R or blood compartment) of volume V_R and intestine compartments are interconnected

Figure 16.4 Physiologically based pharmacokinetic (PBPK) intestine models: (a) the traditional model or TM and (b) the segregated flow model or SFM, with the intestine as the only elimination tissue. For the SFM, the intestine tissue is divided into the enterocyte (en) region and the serosal (s) region. See text for description of flows, volumes, and assumptions.

by the intestinal or portal venous blood flow, Q_I or Q_{PV} , and V_{intb} , V_{int} , and V_{lumen} represent volumes of the various intestinal subcompartments, intestinal blood, the intestine, and the lumen, respectively. The drug is delivered under constant blood flow (Q_I) into the intestinal blood via the superior mesenteric artery and exits the intestine into the portal vein. The influx of the drug into the intestinal tissue from the blood is characterized by the transport clearance parameter, CL_{d1}^I . Once the drug traverses the basolateral membrane to enter the tissue, it undergoes biotransformation to form metabolites (denoted by the intestinal metabolic clearance, $CL_{int,met1,I}$ and $CL_{int,met2,I}$) or excretion (denoted by intrinsic secretion clearance $CL_{int,sec,I}$) or may be effluxed back to the circulation (denoted by transport clearance CL_{d2}^I). The absorption rate constant of drug and metabolite from the intestinal lumen is denoted by k_a or $k_a\{mi\}$, and their transit or degradation/metabolism rate constants within the lumen, representing net loss in lumen, are denoted by k_g or $k_g\{mi\}$, to denote an ineffective absorption.

Owing to failure of the TM to predict route-dependent intestinal metabolism, namely little or no metabolism occurring after systemic dosing but notable metabolism following oral dosing, the segregated flow model (SFM) has been subsequently developed (Fig. 16.4b). The development was sparked by observations on morphine (M) glucuronidation to the 3-glucuronide (M3G) in the perfused rat intestine preparation: the lack of [3H]M3G formed after systemic [3H]M administration and the abundance of [3H]M3G (13% dose) formed after [3H]M administered intraduodenally support the hypothesis of route-dependent metabolism [13]. According to the SFM, a reduced blood flow rate perfuses the enterocyte layer, reducing the rate of drug delivery to intestinal enzymes or secretory sites and rendering lower values of intestinal clearance [14]. However, during oral absorption, the entire orally administered dose must traverse the enterocyte layer before the substrate enters the circulation. The differential exposure with the route of administration results in different extents of exsorption and metabolism and contributes to the observation of route-dependent metabolism. The SFM is consistent with intestinal blood patterns of about 60–70% of the intestinal flow [115] perfusing the nonabsorptive and nonmetabolizing serosal and submucosal regions, and only a low, partial flow ($\sim 18\%$ [116], 5–7% [117,118], or 10–30% [119,120]) of the intestinal blood perfuses the absorptive and metabolizing enterocyte region where the metabolic enzymes and the transporters are located [14]. The SFM further provides a view that was adopted in commercially available programs such as Simcyp[®] [121]. As shown in Fig. 16.4b, the parent drug and metabolite are delivered under constant blood flow ($0.9Q_I$) to the serosal tissue, which is characterized by the transport clearance parameter, CL_{d3}^I and $CL_{d3}^I\{mi\}$, respectively. The parent drug and metabolite can also be effluxed back into serosal blood (CL_{d4}^I or $CL_{d4}^I\{mi\}$), respectively.

Utilizing these two models, Sun and Pang [18,122] solved the AUC terms for the parent drug and metabolite (Table 16.4). The solutions for AUC_{po} , $AUC_{po}\{mi\}$, and $AUC_{iv}\{mi\}$ are found to be identical for the TM and SFM, whereas for AUC_{iv} , the solution is similar except that Q_I exists in the solution for the TM and Q_{en} for the SFM. The secretory intestinal intrinsic clearance of the drug ($CL_{int,sec,I}$) is found associated with the term $(1 - F_{abs})$, where F_{abs} is the fraction absorbed or $k_a/(k_a + k_g)$. When the absorbed fraction, F_{abs} , is high (~ 1) due to the high k_a relative to k_g , net secretion is effectively reduced to zero. Moreover, AUC_{po} and AUC_{iv} are found to be inversely related to the sum of $(1 - F_{abs})CL_{int,sec,I}$ and $CL_{int,met,I}$, whereas $AUC_{po}\{mi\}$ and $AUC_{iv}\{mi\}$ are further related inversely to the sum of $(1 - F_{abs}\{mi\})CL_{int,sec,I}\{mi\}$ and

$CL_{int,met,I}\{mi\}$. Owing to the effective modulation of absorption on $CL_{int,sec,I}$ by F_{abs} , changes in $CL_{int,met,I}$ would exert a greater effect on drug bioavailability compared to $CL_{int,sec,I}$ [122]. The difference in flow between models imparts a substantial influence on the intestinal clearance of flow-limited substrates. The SFM predicts a markedly higher extent of intestinal metabolism for oral compared to intravenous dosing, and the TM predicts a higher intestinal metabolism compared to that for the SFM.

Owing to the varying segmental distributions of absorptive and secretory transporters and metabolic enzymes along the small intestine, the single intestinal compartments of the TM and SFM have been expanded into three equal segmental compartments, segmental, TM and the segmental, SFM [123]. These advanced PBPK models have been applied to predict the impact of metabolic and transporter activities in different segments of the intestine on the intestinal drug clearance and oral drug availability [123].

16.5.3 The Kidney

The kidney is one of the major excretory organs of drugs and metabolite and exhibits a significant capacity to metabolize drugs [12,124,125]. The isolated kidney perfusion is one technique that allows metabolic and excretory events to be examined simultaneously under controlled conditions and described by PBPK modeling. In the PBPK kidney model, the drug is delivered into renal tubular cells by the slightly reduced renal flow ($Q_K - GFR$) due to removal of plasma water by glomerular filtration (of rate, GFR), and, on the reabsorption of water, the returning flow to the reservoir ($Q_K - Q_U$) is the difference between the renal blood/plasma flow and urinary flow, Q_U (Fig. 16.5). Drug influx and efflux clearances by transporters at the basolateral membrane are described as CL_{in}^b and CL_{ef}^b , respectively. The drug that is reabsorbed or secreted in the urine compartment by transporters at the apical or luminal membrane with influx and efflux clearances denoted by CL_{in}^l and CL_{ef}^l , respectively. The drug enters the renal cell either at the basolateral membrane with influx clearance, CL_{in}^b , or by reabsorption at the apical membrane (with reabsorptive clearance, CL_{in}^l). In the renal tissue, the drug may undergo metabolism denoted by $CL_{int,met,K}$ to form the primary metabolite, Mi , which may undergo transport at the basolateral and apical membranes or further metabolism, denoted by $CL_{in}^b\{mi\}$, $CL_{ef}^b\{mi\}$, $CL_{in}^l\{mi\}$, $CL_{ef}^l\{mi\}$, and $CL_{int,met,K}\{mi\}$, respectively.

The kidney PBPK model has been utilized to explain levels of drugs that undergo glomerular filtration, saturable secretion, and/or reabsorption and effects of inhibitors such as probenecid at the basolateral membrane [126–130]. The change in drug reabsorption due to changes in pH was also applied in this model [128]. PBPK models are used to describe renal metabolite formation and immediate excretion and the existence of a nonconstant renal metabolite clearance denoting the kidney as a metabolite formation organ [12,84].

One advantage of using the PBPK kidney modeling approach is the ability to examine the effects of renal transporters and enzymes on renal clearance, CL_R , of a drug. Table 16.5 shows the AUC and CL_R for the kidney with possible alternate pathways for the drug and its metabolite. The basolateral (CL_{in}^b and CL_{ef}^b) and luminal (CL_{in}^l and CL_{ef}^l) transporters, the GFR , Q_K , and Q_U all do influence the AUC and CL_R of the drug. The ratio of CL_R and $f_p GFR$, or fractional excretion (FE) or excretion ratio (ER), denotes whether reabsorption, net filtration, or secretion takes place by deviation of the ratio from below unity to unity or to above unity. When metabolism is relevant,

Figure 16.5 Physiologically based pharmacokinetic (PBPK) kidney model, with kidney as the only elimination organ. See text for description of the model.

$CL_{\text{int,met,K}}$ is present in the AUC and CL_R solutions, and the solutions become more complicated (Table 16.5). Indeed, the presence of metabolism as the alternate pathway will affect excretory clearance and further change the FE or ER ratio [91].

Renal PBPK modeling approaches have exploited the concept of drug transport and metabolism to examine the kinetics of a drug and its metabolite(s) in the kidney. In a single-pass kidney perfusion study, the extraction ratio ($E\{\text{mi},P\} = 0.39$) of hippurate (metabolite formed from its precursor drug, benzoate) was found to differ from the extraction ratio when hippurate ($E\{\text{pmi}\} = 0.24$) was administered [131]. The lower extraction ratio of the administered hippurate was explained by the renal PBPK model, which described a rapid hippurate formation within the renal cells and a high secretion activity of hippurate at the apical membrane; in contrast, the preformed hippurate would first undergo filtration before reaching the peritubular cells and partially evade the high secretory sites.

A renal PBPK model has been applied to examine the metabolism and excretion of enalapril, an ACE inhibitor. In both single-pass and recirculating isolated rat kidney perfusion, a higher extraction ratio of enalaprilat, the dicarboxylic acid metabolite, was observed when the precursor, enalapril, was administered compared to that when preformed enalaprilat was administered. The major reason is the presence of a membrane barrier that retards enalaprilat entry into the kidney and back efflux to blood [12,84,89,125,132]. As a result, preformed enalaprilat was mainly eliminated by GFR. For the metabolite enalaprilat that was formed within the kidney, a much higher and time-dependent renal clearance was observed. The time-dependent excretion clearance

TABLE 16.5 Solutions for AUC_{iv} and CL_R with and without Renal Metabolism in the Kidney Only

AUC and CL_R Terms	Solutions
AUC_{iv} (no metabolism)	$AUC_{iv} = Dose_{iv} \frac{\{(\mathcal{Q}_K - \mathcal{Q}_U) [CL_{in}^1 CL_{ef}^b + \mathcal{Q}_U (CL_{ef}^b + CL_{ef}^1)] + \mathcal{Q}_U f_B CL_{in}^b CL_{ef}^1\}}{\mathcal{Q}_U f_B [\mathcal{Q}_K CL_{in}^b CL_{ef}^1 + GFR (\mathcal{Q}_K - \mathcal{Q}_U) (CL_{ef}^b + CL_{ef}^1)]}$
CL_R (no metabolism)	$CL_R = \frac{\mathcal{Q}_U f_B [\mathcal{Q}_K CL_{in}^b CL_{ef}^1 + GFR (\mathcal{Q}_K - \mathcal{Q}_U) (CL_{ef}^b + CL_{ef}^1)]}{(\mathcal{Q}_K - \mathcal{Q}_U) [CL_{in}^1 CL_{ef}^b + \mathcal{Q}_U (CL_{ef}^b + CL_{ef}^1)] + \mathcal{Q}_U f_B CL_{in}^b CL_{ef}^1}$
AUC_{iv} (with metabolism)	$AUC_{iv} = \frac{Dose_{iv} \{(\mathcal{Q}_K - \mathcal{Q}_U) [CL_{in}^1 (CL_{ef}^b + CL_{int,met,K}) + \mathcal{Q}_U (CL_{ef}^b + CL_{ef}^1 + CL_{int,met,K})] + f_B CL_{in}^b [\mathcal{Q}_U CL_{ef}^1 + CL_{int,met,K} (CL_{in}^1 + \mathcal{Q}_U)]\}}{GFR f_B (\mathcal{Q}_K - \mathcal{Q}_U) [CL_{int,met,K} (CL_{in}^1 + \mathcal{Q}_U) + \mathcal{Q}_U (CL_{ef}^b + CL_{ef}^1)] + \mathcal{Q}_K f_B CL_{in}^b [\mathcal{Q}_U CL_{ef}^1 + CL_{int,met,K} (CL_{in}^1 + \mathcal{Q}_U)]}$
CL_R (with metabolism)	$CL_R = \frac{GFR f_B (\mathcal{Q}_K - \mathcal{Q}_U) [CL_{int,met,K} (CL_{in}^1 + \mathcal{Q}_U) + \mathcal{Q}_U (CL_{ef}^b + CL_{ef}^1)] + \mathcal{Q}_K f_B CL_{in}^b [\mathcal{Q}_U CL_{ef}^1 + CL_{int,met,K} (CL_{in}^1 + \mathcal{Q}_U)]}{(\mathcal{Q}_K - \mathcal{Q}_U) [CL_{in}^1 (CL_{ef}^b + CL_{int,met,K}) + \mathcal{Q}_U (CL_{ef}^b + CL_{ef}^1 + CL_{int,met,K})] + f_B CL_{in}^b [\mathcal{Q}_U CL_{ef}^1 + CL_{int,met,K} (CL_{in}^1 + \mathcal{Q}_U)]}$

of formed enalaprilat was partially due to the immediate excretion of the enalaprilat that was formed *in situ* in the kidney (the time-dependent component that is dependent on drug concentration in the kidney) and partially due to filtration of the recirculating metabolite (component reflected by preformed metabolite); the sum contributes to the observed renal clearance of the formed metabolite [12,84,125]. This clearance differs from the conventional estimate of the clearance of the preformed metabolite [12].

16.6 WHOLE-BODY PBPK

Whole-body PBPK models provide an understanding of the behaviors of drugs and metabolites based on physiological parameters. Usually, when the intestine, liver, and kidney, major drug eliminating organs/tissues, are included together with highly perfused, poorly perfused, and adipose tissues (Fig. 16.6), mechanisms governing removal and the rate-limiting step (e.g., metabolism by enzymes, influx by transporters, and secretion via apical transporters) are revealed. In this occasion, the renal clearance may be embedded in the blood compartment to describe the parallel loss of drug from

Figure 16.6 Whole-body, physiologically based pharmacokinetic (PBPK) model, with drug and metabolite being excreted by the kidneys with CL_R and $CL_R\{mi\}$, and metabolized either in the intestine or the liver. Sequential metabolism/excretion of the formed metabolite occurs with the organ of formation, and the drug may be further metabolized to other metabolites. Only the intestinal TM is presented here, but the SFM is also considered (Table 16.6). See text for description of the model.

the kidney. The PBPK models provide an account of how the processes of transport and metabolism modulate the kinetics of the drug and its metabolites, and how drug behavior further affects the kinetics of the metabolites (Table 16.6).

The analytical solutions for the AUC and $AUC_{\{mi,P\}}$ solved for the drug and the formed metabolite divulge how the variables affect the exposure and fates of the drug and the formed metabolite within metabolite formation organs and in blood/plasma (Table 16.6). The solutions reveal that the effect of intestinal secretion is nullified when avid absorption takes place (Table 16.6). It may be further discerned that the ratio of $AUC_{po\{mi,P\}}/AUC_{iv\{mi,P\}}$ pursuant to drug oral and intravenous administration, corrected for dose, yields the fraction of dose absorbed, F_{abs} , into the portal circulation when either the intestine or the liver is the only drug metabolizing organ, and the dose-corrected AUC_{po}/AUC_{iv} yields the systemic availability, F_{sys} . On division of AUC_{po}/AUC_{iv} by $AUC_{po\{mi,P\}}/AUC_{iv\{mi,P\}}$, one obtains the intestinal or hepatic availability (Table 16.6) [18].

16.6.1 Sequential Metabolism and Metabolite Behavior

The PBPK model is particularly pertinent to describe the sequential elimination of the formed metabolite, asserting that the metabolite, formed *in situ* within the formation organ, is subject to immediate excretion or sequential metabolism to form secondary or tertiary metabolites. The reason that estimation of the AUC of the metabolite, $AUC_{\{mi,P\}}$, is important because the metabolite may possess active or toxic therapeutics effects [86]. Furthermore, one can take advantage of AUC solutions of the parent drug and the formed metabolites and compare the AUC ratio between intravenous and oral administration to estimate the variables important for drug absorption. Some examples on sequential metabolism are listed in Table 16.7.

The whole-body PBPK model approach clearly explains the influence of transporters and enzymes on the AUCs of the parent drug and its formed metabolites in a route-dependent fashion and that the $AUC_{\{pmi\}}$ differs from the $AUC_{\{mi,P\}}$. Pathways of sequential metabolism of the formed primary metabolite (Mi) can exist either within its organ of formation or in additional eliminating organs. Under this situation, the AUCs and clearances of formed (denoted by subscript, mi) and preformed primary metabolite (denoted by subscript, pmi) differ when there is low permeability of the metabolite, resulting in the delay in the kinetics due to the formation step of the formed metabolite and/or competition for the drug in the same or other organs. These differences have been demonstrated both experimentally and theoretically [15,18,102,122,142–144]. The discrepancy is also caused by differences in enzyme/transporter heterogeneity within the organ involved in formation or further metabolism of Mi [15,18,86,122]. These differences must be borne in mind when the kinetics of the preformed metabolite is used to predict the kinetics of the formed metabolite, especially for MIST.

16.6.2 Examination of Transporter and Enzyme Interplay

Generalized whole-body PBPK models have been developed to describe the impact of transporters and enzymes on the PK of the parent drug and the disposition of formed metabolites. Not until recently, these models lack the appropriate subcompartments within the organs to describe the influence of different transporters and enzymes on the parent drug and metabolites. Sun and Pang [18] described a whole-body PBPK model

TABLE 16.7 Examples of PBPK Modeling for Sequential Metabolism

Chemicals and Major Metabolic Pathway of Interest	Applications and Features	References
Nicotine → cotinine → polar metabolites	- Studied nicotine disposition in SD rats - Described tissue and plasma kinetics of cotinine, a biomarker for exposure to tobacco smoke - Used <i>in vivo</i> rat nicotine PK study to validate the predictive power of the PBPK model	134
Butadiene → butadiene monoxide → butadiene monoxide glutathione conjugate	- Examined potential carcinogen effect of butadiene, an environmental air pollutant - Validated PBPK model against published observations on butadiene and butadiene monoxide and liver glutathione kinetics in rats and mice <i>in vivo</i> - PBPK model was used to explain species difference in cancer response between mice and rats exposed to butadiene	135,136
Styrene → styrene → styrene-7,8-oxide → styrene-7,8-oxide glutathione conjugate	- Illustrated the carcinogenic potential of styrene due to its active metabolite styrene-7,8-oxide in risk assessment - Included cosubstrate, glutathione, to describe conjugation of styrene-7,8-oxide to its conjugate by glutathione-S-transferase	137
Octamethylcyclotetrasiloxane (D ₄) → short-chain linear siloxanes	PBPK of inhalation kinetics of D₄, a silicon fluid, in humans during rest and exercise	138
Uracil → dihydrouracil → β-ureidopropionate → β-alanine	- Described ¹³CO₂ exhalation after orally administered [2-¹³C]uracil - Reported dihydropyrimidine dehydrogenase as the key enzyme of cytotoxicity of 5-FU - Used [2-¹³C]uracil in identifying patients at risk of 5-FU toxicity	139
Atrazine → chlorotriazines → diaminochlorotriazine → glutathione conjugates	Described oral absorption and oxidative metabolism of atrazine on the blood time course curves of individual chlorotriazines in rat, and the toxic neuroendocrine effects associated with chlorotriazines exposure but not of the nonchlorinated metabolites	140
Dichloromethane (DCM) → formyl chloride → CO	Evaluated two different metabolic hypotheses for DCM toxicity using PBPK modeling for <i>in vivo</i> inhalation gas uptake data exposure in female B6C3F1 mice	141

approach that includes both transporters and enzymes and their impact on the AUC and PK of the parent drug and the formed metabolites. This whole-body PBPK model approach clearly explains the influence of transporters and enzymes on the AUCs of the parent drug and its formed metabolites in a route- and time-dependent fashion (Table 16.6).

There are an increasing number of studies with PBPK modeling that examine effects of the interplay of transporters and enzymes on the blood and target organ exposures of the drug and its metabolites [78]. Watanabe *et al.* [79] reported that changes in pravastatin hepatic uptake greatly altered the plasma concentration but had minimal effect on the concentration in liver, whereas alteration of hepatic efflux transporters would greatly affect liver concentration but not plasma concentration. In another study, Rowland Yeo *et al.* [145] found that enzyme inhibition of triazolam by diltiazem and its metabolite, *N*-desmethyldiltiazem, plays a role in affecting the AUC of triazolam.

16.7 APPLICATIONS OF PBPK MODELS

16.7.1 Prediction of Exposure in Tissue Sites

In principle, PBPK models permit the prediction of the concentration of the parent drug and metabolites in any tissue or target organ. Examples are tumor tissue [146], the fetus [147], the testes [28], or other various tissues [4,134,148,149] within the body, providing additional physiological information and mechanistic answers. In addition, PBPK models are superior over traditional PK models in that they can be used to explain the nonlinear uptake of parent drugs from skin into tissue sites [150], membrane-limited uptake of drugs [151], or the disposition of both the parent drug and its metabolite in tissue sites [152]. Table 16.8 lists examples investigating drug exposure at tissue sites which were described by PBPK models.

16.7.2 Prediction of Pharmacological Activity or Toxicity

PBPK/PD models are also useful for predicting the relationship between drug exposure and pharmacological and/or toxicological effects in target organs to explain pharmacological [154,155] and toxicological outcomes [146,156,157]. By providing a link between tissue concentration and pharmacological and/or toxicological effects, PBPK models can be expanded to form mechanistic PK/PD models [158]. When combined with a mechanistic or empirical PD model (PBPK/PD), the therapeutic outcome or adverse events within a certain population could be predicted before clinical studies. The PBPK/PD model is created when the PBPK model is linked to a pharmacodynamic (PD) model by an equation that reflects the researcher's hypothesis of how the drug participates in the initiation of cellular changes leading to measurable outcomes. The temporal change in the dose metric simulated by the PBPK model is linked with mathematical descriptions of the response process associated with the drug.

Table 16.9 summarizes applications of PBPK/PD model to quantify the relationship between the drug and the pharmacologic effect. A semimechanistic PK–PD model, with incorporation of saturable hepatic elimination on the first-pass extraction as well as a

TABLE 16.8 Examples of Whole-Body PBPK Models that Emphasize Drug Exposure at Tissue Sites

Chemicals	Species	Model	References
5-Flourouraacil (5-FU)	Mouse	Flow-limited model to predict accumulation of 5-FU in human tumor tissues	146
Barbiturates	Rat	Flow-limited compartments for lung, liver, kidney, stomach, pancreas, spleen, gut, muscle, adipose, skin, bone, and heart and membrane-limited compartments in brain and testis barbiturates disposition in different tissues	149
Chlordecone	Rat	Flow-limited model to evaluate the effect of age and dosage on percutaneous absorption and tissue disposition of chlordecone	153
Digoxin	Rat	Flow-limited model to predict the concentrations of digoxin in the heart, liver, skeletal muscle, and plasma	148
Everolimus	Rat	Flow-limited model to predict nonlinear binding of everolimus to red blood cells and tissues, and the highest tissue binding in thymus, skin, and muscle	150
Moxalactam	Rat, dog, and human	Membrane-limited model to explain moxalactam epimerization on the warfarin-binding site of serum albumin	151
Nicotine	Rat	Flow-limited model to predict the nonlinear nicotine elimination in the brain, heart, and lung, suggesting that saturable nicotinic binding sites may be important in nicotine disposition	134
<i>p</i> -Phenylbenzoic acid	Rat	Flow-limited model to predict <i>p</i> -phenylbenzoic acid concentration–time profiles in different tissues of the mother and placenta of the fetuses	147
Thiopental	Dog	Flow-limited model to predict thiopental concentrations in blood, viscera, lean tissue, and adipose tissue	4
Tretinoin	Rat, monkey, and human	Flow-limited model to predict tretinoin pharmacokinetics in plasma and different tissues and to extrapolate across species and routes of administration	152

TABLE 16.9 Examples of Whole-Body PBPK/PD Models

Applications and Features		References
<i>Quantified Relationship Between Drug and Effect</i>		
Diisopropylfluorophosphate (DFP)	Effect of DFP on acetylcholinesterase activity	160
Glycyrrhetic acid	Inhibition of 11 β -hydroxysteroid dehydrogenase activity	157
Chlorpyrifos	Evaluated the chlorpyrifos toxicity, pharmacokinetics, and tissue cholinesterase inhibition in neonatal and adult rats	161
Carbofuran	Characterized AChE inhibition from carbofuran exposure	162
<i>Predicted Toxicologic Interactions</i>		
Trichloroethylene and 1,1-dichloroethylene	Predicted the toxicologic interactions and define the interaction threshold	163
Kepon and carbon tetrachloride	Predicted the toxicologic interactions and define the interaction threshold	164
<i>Linked Drug Dosimetry with Biological Response</i>		
Trichloroethylene	Evaluated the organ toxicity from oral exposure and inhalation	165
Chlorpyrifos and diazinon	Determined dosimetry and cholinesterase inhibition	161
Diazinon and its metabolites	Determined dosimetry and cholinesterase inhibition	166
Carbaryl and its metabolites	Predicted the carbaryl-induced inhibition of cholinesterase activity	167
<i>Evaluated Organ Toxicity Resulting from Metabolites</i>		
Trichloroethylene	Evaluated the organ toxicity resulting from metabolites	165
<i>Performed Various Forms of Extrapolation</i>		
Acrylamide	Extrapolated data from rodent to human	168,169
Brivaracetam	Extrapolated data from rodent to human	170

higher intrinsic clearance in female patients, resulted in the best fit to the time course of salivary artemisinin concentrations after repeated dosing and the number of parasites in patients treated with the drug [159]. The effect of diisopropylfluorophosphate (DFP) on acetylcholinesterase (AChE) activity in mouse and rat was studied using a PBPK/PD model, which accurately predicted the AChE activity similar to those found *in vivo* based on the blood concentration of DFP [160].

The PBPK/PD model may also be used to evaluate organ toxicity developed from trichloroethylene (TCE) metabolites [165]. To date, there are over 250 scientific research papers (searched via PubMed, PBPK + toxicity) using similar PBPK modeling approaches to predict and explain the toxicity of drugs, environmental chemicals, or its metabolites in animal or human models [171–173]. Table 16.10 lists examples of PBPK models that were used to predict chemical exposure and toxicity *in vivo*. Doerge *et al.* [168] used a PBPK/PD model to translate the findings from rodent neurotoxicity and cancer risks into estimates of risks in human acrylamide exposure through diet. PBPK/PD models are also useful tools for linking drug dosimetry with biological response and for evaluating the risk associated with a given drug exposure. Barton and Clewell [165] used a PBPK/PD model to evaluate eye malformation, liver effects, immunotoxicity, and kidney toxicity from oral exposure and neurological, liver, and kidney effects by inhalation with dose metrics for TCE.

Other studies had estimated toxicological exposures of chemicals and drugs that ranged from phthalate esters found in drinking water to acetonylacetone (a neurotoxic industrial solvent), trace metals such as iodine and chromium, and therapeutic drugs such as digoxin [28,171] in target organs. Using the appropriate physiological parameters, Sweeney *et al.* [180] were able to relate the incidence of liver adenomas and carcinomas to the liver exposure (AUC) of trichloroacetic acid, the toxic metabolite of perchloroethylene (a solvent used in dry cleaning), in a mouse PBPK model. In another toxicological study, a generalized rat whole-body PBPK model, focusing primarily on the liver, examined the involvement of transporters such as Mrp2 on the liver exposure of pentachlorobipenyl, a carcinogenic environmental pollutant and a substrate of Mrp2, and liver carcinogenicity [179]. Toxicologic interactions have been predicted with PBPK/PD modeling that defined the interaction threshold between TCE and 1,1-dichloroethylene (1,1-DCE) [163] and between kepone and carbon tetrachloride (CCl₄) [164].

16.7.3 Effects of Disease States, Pregnancy, Age, and Polymorphism

PBPK modeling approaches in toxicological studies not only focus on exposure of toxicants to healthy adults but also apply to pregnant women [182], children [183], the elderly [184], and the study of genetic polymorphism [185]. PBPK models enable us to evaluate the drug concentration–time profile for any dose and administration route under various physiological conditions: disease state, pregnancy, age, and polymorphism.

There have only been a few studies that relate to PK of drugs in disease states with PBPK modeling. For instance, a PBPK model describing drug kinetics in interstitial fluid in patients with hemorrhagic shock followed by fluid resuscitation was used to evaluate amoxicillin and clavulanate PK [38]. The predictions fit the data well in most instances and were consistent with observed clinical data. A PBPK model adequately described altered midazolam kinetics in elderly patients undergoing

TABLE 16.10 Examples of Whole-Body PBPK Models that Emphasized Drug Toxicity

Chemicals	Species	Model	References
1,1,1,3,3-Pentafluoropropane	Human	Flow-limited model to explain that exposure of 1,1,1,3,3-pentafluoropropane did not result in detection of the metabolite TFPA in urine, suggesting little or no metabolism	174
Arsenic	Mouse	Flow-limited model to explain lack of change in the apparent volume of distribution and tissue-plasma concentration ratios of dimethylarsonic acid after acute and chronic exposure to arsenic	175
Chloroethane	Rat, mouse, human	Flow-limited model to describe different rates of metabolism of chloroethane by glutathione-S-transferase in different species, consistent with observations on uterine tumors	25
Dibromoacetic acid	Rat	Membrane-limited model for aggregated tissue, kidney, and liver and liver metabolism of dibromoacetic acid in the toxicity or carcinogenicity in liver	176
Doxorubicin	Dog	Flow-limited model to explain increase in doxorubicin exposure in ABCB1 (null) dog that may lead to GI toxicosis	177
Molinate	Rat, human	Flow-limited model to predict molinate concentrations of the rat blood and testes compartment and testicular toxicity	178
Pentachlorobipenyl (PCB126)	Rat	Flow-limited model to relate AUC of PCB126 in liver and incidence of liver toxicity	179
Phthalic acid diesters	Rat	Flow-limited model to predict that plasma monobutyl phthalate kinetics are sensitive to glucuronidation and enterohepatic recirculation	28
Trichloroacetic acid	Mouse	Flow-limited model to assess at trichloroacetic acid liver (AUC) exposure to risk of liver adenomas and carcinomas	180
Trichloroethylene	Mouse	Flow-limited model to relate extents of metabolites formed from trichloroethylene in liver to cause hepatomegaly	181

orthopedic surgery due to increased f_p values and changes in volume of distribution and clearance as a result of blood loss and significant reduction in albumin concentration when compared to normal patients [37]. When PBPK modeling was applied to predict the outcomes of liver cirrhosis, a disease characterized by a decrease in functional hepatocytes, lowered circulating plasma proteins, and altered hepatic blood flow patterns due to the development of portacaval shunts, some success was found [186].

There have also been attempts to apply a PBPK model to describe the effect of renal failure on drug disposition. Tsuji *et al.* [36] developed a PBPK model to predict elevation of plasma and tissue levels of cefalozin, a β -lactam antibiotic, in rabbits with renal failure, and obtained good correlation between predicted and observed tissue concentrations. A PBPK model proposed by Harrison and Gibaldi [35] was used to assess digoxin PK in the dog with renal failure, and a scale-up with the dog model to human was partially successful in predicting digoxin kinetics in patients with renal failure. In renal disease state, a concomitant reduction in hepatic drug metabolizing activities is often found [187,188]. Moreover, changes in transporters [189,190] were found associated with renal [187] and other diseases: inflammatory bowel diseases and inflammation and infection wherein cytokines are elevated [190,191]. These accompanying changes in transporter/enzyme function further add complexities to the quantitative prediction with regard to disease-related factors that may limit use of PBPK models, unless the changes are readily identified [192].

Since drug distribution could be altered in pregnancy [193], PBPK models for pregnancy have been used to predict the concentrations of drugs in maternal tissues, the placenta, and/or the fetus [193–198] (Table 16.11). Gabrielsson and colleagues, in particular, had reported on the effects of pregnancy on methadone [197], theophylline [196], pethidine (meperidine) [198], and morphine [195] kinetics in the rat with a PBPK model. Additional reports of PBPK models on pregnancy are listed in Table 16.11.

The prediction of drug exposure in special populations (different age groups including neonates, infants, children, and adult) is often made with PBPK modeling [199–201]. A general PBPK model has been used for the prediction of the PK of model substrates, such as theophylline for CYP1A2 and CYP2E1 and midazolam for CYP3A4, in neonates to young adults by considering the age-related changes in unbound intrinsic hepatic clearances [199], with predictions that were in good agreement with literature data. Furthermore, Edginton *et al.* [200] and Johnson *et al.* [201] had applied PBPK models to assess the age-related physiological changes in younger children for 5 (paracetamol, alfentanil, morphine, theophylline, and levofloxacin) and 11 drugs (midazolam, caffeine, carbamazepam, cisapride, theophylline, diclofenac, omeprazole, *S*-warfarin, phenytoin, gentamycin, and vancomycin), respectively. The predictions were also in good agreement with observed data and showed that the PBPK models are superior to the method of allometric scaling. Thompson *et al.* [202] further reviewed a physiological database useful for PBPK modeling of the healthy and impaired elderly population.

In addition to the above conditions, PBPK models have also been used to simulate effects of genetic variations [79] and enzyme/transporter heterogeneity [92,95] on drug disposition in eliminating organs and the consequences on pharmacological and toxicological effects [39]. Differences in metabolism due to enzyme abundance (e.g., in the case of CYP2D6 poor metabolizers) or differences in intrinsic enzyme activities (e.g., CYP2C9 variants) could be included in PBPK modeling. Inoue *et al.* [203] had found

TABLE 16.11 Examples for Whole-Body PBPK Model for Pregnancy

Drug	Model	Species	References
Morphine	Flow limited for all tissue; membrane limited (fetus)	Rat	196
Methadone	Flow limited for all tissue; membrane-limited compartments for maternal brain/fetus	Rat, human	197
Pethidine (meperidine)	Flow limited for all tissue; membrane limited for fetus	Rat, human	198
<i>p</i> -Phenylbenzoic acid	Flow limited for some tissue; membrane limited for placenta, brain, gut, spleen, muscle, fat, and skin	Rat	147

Theophylline	Flow limited for all tissue; membrane-limited compartments for maternal brain/fetus	Rat	195

ethnic differences in the *in vivo* clearances of alprazolam, caffeine, chlorzoxazone, cyclosporine, midazolam, omeprazole, sildenafil, tolbutamide, triazolam, *S*-warfarin, and zolpidem with the virtual clinical simulator, Simcyp[®], which contains background information on the abundance of various P450s and different population distributions of their alleles to account for genetic and ethnic differences in metabolism. The interesting phenomenon is well described by Dickinson *et al.* [204] using the Simcyp[®] simulator to predict the impact of genetic polymorphism of CYP2C9 on the PK and PD of *S*-warfarin. Recently, a study on genetic polymorphism of the anionic transporter organic anion transporting polypeptide 1B1 (OATP1B1) examined pravastatin plasma concentrations with PBPK modeling and showed sensitivity of systemic exposure of pravastatin to hepatic uptake [39].

16.7.4 Drug–Drug Interactions

The accurate prediction of potential risks for DDIs is important because DDIs are responsible for reduced efficacy or increased adverse events. DDIs usually result from the induction or inhibition of metabolic enzymes, mostly P450s, or transporters, or from a change in protein binding. Inhibition may involve either simple competitive or time-dependent (mechanism-based) inhibitory kinetics, the latter of which involves destruction of the enzyme/transporter that leads to a reduction in metabolism/transport [17]. Induction of the enzyme/transporter usually involves transcriptional and translational changes that lead to new protein synthesis. Alternately, changes in endogenous substrates, for example, cytokines, or ligands of nuclear receptors can also affect enzyme and transporter levels [190].

A general equation exists for the AUC ratio in the presence of the interactant (or perpetrator) and under control conditions ($AUC_{(I)}/AUC_{(C)}$) to reflect inhibition or

induction of a victim drug:

$$\frac{AUC_{(I)}}{AUC_{(C)}} = \frac{1}{\left(\frac{f_m f_{m,CYP}}{\left(\frac{CL_{int(C)}}{CL_{int(I)}} \right)} \right) + (1 - f_m \cdot f_{m,CYP})} \quad (16.17)$$

where f_m , $f_{m,cyp}$, $CL_{int(C)}$, and $CL_{int(I)}$ are the fraction of the dose metabolized by all P450 isoforms, the fraction of the dose metabolized by each specific P450 enzyme, and the intrinsic clearances under control and inhibited conditions, respectively [205–207].

For reversible metabolism, the ratio of $CL_{int(C)}/CL_{int(I)}$ equals

$$\frac{CL_{int(C)}}{CL_{int(I)}} = 1 + \frac{[I]}{K_I} \quad (16.18)$$

where $[I]$ is the inhibitor concentration and K_I is the inhibition constant.

For time-dependent (mechanism-based) inhibition, the ratio of $CL_{int(C)}/CL_{int(I)}$ equals

$$\frac{CL_{int(C)}}{CL_{int(I)}} = 1 + \frac{k_{inact}}{K_I} \frac{[I]}{k_{deg}} \quad (16.19)$$

where k_{inact} and k_{deg} are the rate constants for inactivation and degradation of the enzyme, respectively [208,209].

For induction, the ratio of $CL_{int(C)}/CL_{int(I)}$ equals

$$\frac{CL_{int(C)}}{CL_{int(I)}} = 1 + \frac{E_{max}[I]}{EC_{50} + [I]} \quad (16.20)$$

where E_{max} and EC_{50} are the maximum induction activity and the concentration of inducer associated with half maximum induction, respectively [210]

These types of static AUC comparisons, however, have been criticized since the inhibitor concentration or $[I]$, taken as C_{max} or unbound C_{max} [211], does not reflect the concentrations of drug and interactant at the site of interaction of the enzyme/transporter. Furthermore, the interaction may lead to changes in protein levels of the enzymes/transporters or consequences on the synthesis and degradation rate. Under the same circumstances, the concentration of the interactant may also be changed.

DDI predictions with the use of PBPK modeling on reversible inhibition afford more accurate predictive ability than conventional methods (Eq. 16.18) that fail to describe the $[I]/K_I$ ratio, given that $[I]$, or the concentration of the inhibitor at the enzyme site, is not static but changes with time and mutual inhibition. Some studies included PBPK models for simulating the changes in drug kinetics with reversible DDIs [211–213]. Furthermore, a whole-body PBPK approach based on a gut compartmental absorption and transit (CAT) model showed improved predictions on DDIs of midazolam, the CYP3A4 substrate, which was coadministered with ketoconazole or verapamil [214]. In comparison, the conventional, static approach with the use of $[I]/K_I$ overpredicted levels of midazolam, whereas predictions by the PBPK model were superior (within

TABLE 16.12 Use of Whole-Body PBPK Models for DDIs

Drug	Combination Drug (Inhibitor)	Species	References
2',3'-Dideoxyinosine	Pentamide	Rat and human	212

Triazolam	Erythromycin	Human	211
Warfarin	Bromosulfophthalein	Rat	218

twofold for AUC and $C_{\max}$), regardless of administration route, dosage, and/or coadministration with an inhibitor [214]. These examples are summarized in Table 16.12.

PBPK models that entail dynamic changes in concentration of the perpetrator and victim drug have also been proposed [145,216,217,219]. For example, a simplified PBPK model incorporating two elimination pathways for intestinal and hepatic metabolism of HIV protease inhibitors, including ritonavir, amprenavir, saquinavir, nelfinavir, and indinavir, was constructed to describe multiple HIV therapy and, subsequently, the interaction due to multitherapy with the protease inhibitors [217]. The observed and predicted AUCs according to the PBPK model were in good agreement after oral administration in rats. Zhang *et al.* [219] described changes in intestinal and hepatic P450 protein levels together with changes in activity toward midazolam metabolism due to the mechanism-based inhibition by diltiazem and its major metabolite and predicted the transient and dynamic changes. Quinney *et al.* [216] developed a simple PBPK model, incorporating hepatic and intestinal metabolism by CYP3A and non-CYP3A4 mechanisms, to predict the mechanism-based inhibition of clarithromycin on midazolam metabolism and explained the nonlinear PK of clarithromycin. In another study, Rowland Yeo *et al.* [145] found that the simultaneous competitive and time-dependent enzyme inhibition of triazolam by diltiazem and its metabolite, *N*-desmethyldiltiazem, played a significant role in altering triazolam blood AUC. Clearly, the impact of transporters and enzymes on the exposure of drugs and its metabolite in plasma and target organs are avidly being examined by whole-body PBPK models. Their inclusion, especially under conditions of prolonged inhibition [220], needs to be further investigated.

16.8 CONCLUSIONS

PBPK models are comprehensive models that consider the physiology, anatomy, and biochemistry of the body as well as physicochemical properties of the drug and metabolite. The understanding of absorptive, distribution, metabolic, and excretory

processes through fitting and simulation of concentration–time profiles of plasma and target tissues in generic PBPK models, as discussed in this chapter, allows one to make predictions in target sites and allows proper projection of the effects of age, pregnancy, disease states, and DDIs. Currently, there is an impetus for pharmaceutical industry and FDA to utilize PBPK modeling and commercialized software in drug development and for the prediction of DDIs, genetic polymorphism, and disease states, with animal and *in vitro* studies for the scale-up of transporter and enzyme function to predict transport and metabolic activities in man *in vivo*. These activities have greatly facilitated an understanding of processes affecting the concentration time course, AUC, and clearance of drugs and their metabolites. The increasing use of PBPK modeling in drug development, clinical pharmacology, and risk assessment is a clear testament of the great utility of PBPK modeling in pharmaceutical research.

17.1 SUMMARY

Pharmacodynamics (PD) is the study of physiological effects of drugs on the body and their mechanisms of actions. It provides the basis for rational therapeutic use of drugs and the design of new and superior therapeutic agents [1]. PD comes from the Greek word for “drug,” “pharmakon,” and dynamics means “variation in intensity.” On the other hand, pharmacokinetics (PK) deals with how the body handles the drug after it is absorbed and involves disposition, that is, distribution, metabolism, and excretion processes. For example, an orally administered anticonvulsant drug has to enter the brain after crossing intestinal, hepatic, and blood–brain barriers. The drug has to reach its site of action (brain) in sufficient concentrations and duration to interact with a specific target (i.e., receptor) to produce the desired effect. The drug concentration measured in plasma is more reflective of drug concentration at the site of action than dose, because the dose–response relationship is confounded by PK variables, including

bioavailability, nature of dose–concentration relationships, and formation of active metabolites.

The effect of the drug can be measured as a clinical end point or using a biomarker. The effect of the drug on clinical end point may require studies of extended duration to manifest, for example, increase in survival time, prevention of stroke, and prevention of bone fracture. In these situations, biomarkers may help track the progress of therapy. For example, in the case of an antihypertensive drug trial, blindness, renal failure, and premature mortality can serve as clinical end points and can be measured after prolonged treatment. A simpler biomarker would be blood pressure changes, which are reduced by treatment with an antihypertensive drug. Adiponectin, blood glucose, or binding of a positron emission tomography (PET) ligand to a specific receptor could also serve as biomarkers to evaluate target modulation by a drug candidate. Other PD measures such as QT interval, liver function tests, and white blood cell count can serve as safety biomarkers.

Quantitation of dose–effect relationship was started in 1910 by Hill [2] when he described the association of hemoglobin and oxygen using a relationship that is more widely known as the *Hill equation*. The $E_{\max}$ model used commonly in all PD models was derived from the Hill equation [3]. This concept was first applied by Clark [4] to evaluate the dose–effect relationship of drugs. The hyperbolic nature of the function describes lack of a dose proportional effect after a given dose. Quantitative analysis of the dose–effect relationship has evolved over the years. A significant advancement in PD modeling was to link the PK and PD models to have a better understanding of the time course of PD effect [5]. Another advancement in PD modeling was a method to account for temporal delay observed in pharmacological response when compared to plasma concentrations [6]. Over the years, many types of mechanistic PD models have led to better understanding of different biomarkers and the importance of measuring the right biomarker to predict the clinical response and aid in the design of better clinical trials.

In this chapter, we describe the basic tenets of pharmacodynamics (drug–receptor interactions and agonists vs antagonists), the relative importance of biomarkers, and provide a summary of basic PD models reported in the literature.

17.2 MECHANISMS OF DRUG ACTION

Pharmacological response is initiated by the interaction between a drug and a binding site on a macromolecule in a tissue. This macromolecule is known as the *drug receptor*. The drug–receptor interaction results in a cascade of different steps within the cell, which ultimately leads to a physiological response:

Receptor is a cellular macromolecule or an assembly of macromolecules, which is concerned directly and specifically with chemical signaling between and within cells [7]. Most receptors are proteins (>90%), except some targets such as DNA. These receptors act as a recognition site and messenger to transfer information from the

outside of the cell to the cytosol. The regulatory effects of a receptor may be exerted directly on its cellular targets, effector proteins, or may be conveyed by intermediary cellular signaling molecules called *transducers*. The receptor, its cellular target, and any intermediary molecules are referred to as *mediators* of the signal-transduction pathway. Frequently, the proximal effector protein is not the ultimate target but rather is an enzyme or transport protein that creates, moves, or degrades a small metabolite (e.g., a cyclic nucleotide) or ion (e.g., Ca^{2+}) known as *second messenger*, which will convey information to a variety of targets. The detailed understanding of the signal-transduction pathways helps us design better molecules that interact with different cellular targets to modify physiological and/or pathological processes. It is very challenging to establish that a certain molecular interaction is indeed the one triggering the particular effect. In this respect, genetically modified models such as receptor knock-out animals are proving increasingly useful. For example, a lack of effect of a drug in mice lacking a particular target can provide strong support that the effects of the drug are mediated by that particular target [8].

The cellular proteins are either human genome-derived proteins or belong to pathogenic organisms. In 2002, after sequencing of the human genome, approximately 8000 targets of pharmaceutical interest were estimated. Only a small fraction of those targets is modulated by approved drugs. In 2006, Imming *et al.* catalogued 218 molecular targets for approved drug substances under different target families: enzymes, G-protein-coupled receptors (GPCRs), nuclear hormone receptors, cytokine receptors, ion channels, transport proteins, and so on. Altogether, it suggests that a very large number of putative drug targets remain to be explored [9,10].

During the process of drug discovery, the discovery teams design potential drug candidates that will have a desired pharmacological effect on the human body. If we look at processes at the molecular level in the human body, we would see multiple simultaneous chemical reactions taking place, keeping the systems healthy and functional. The administered agent on reaching its target site will interfere with these chemical reactions to produce a specific effect. The interaction of a drug with a macromolecular target involves a process known as *binding*. There are usually specific areas in the macromolecule where interactions take place, and they are known as the *binding sites*. The interaction of the drug with its target is mediated through electrostatic or ionic bonds, hydrogen bonds, van der Waals interaction, dipole–dipole interactions, and hydrophobic interactions. None of these bonds is as strong as the covalent bond that makes the structure of the molecule, and so they can form and get dissociated. This means that equilibrium is reached between the bound and unbound drugs and its target. Drugs having a large number of interactions are likely to remain bound longer than those that have only a few. Few drugs form irreversible covalent bonds with their receptor. For example, aspirin binds covalently to cyclooxygenase enzyme and prevents formation of thromboxane. The effect will continue until new cyclooxygenase enzyme is synthesized. Other examples include proton pump inhibitors (e.g., omeprazole) that bind irreversibly to $\text{H}^+ \text{K}^+$ -ATPase pumps and block gastric acid secretion.

When the drug molecule combines with the receptor, there might be a delay in the response depending on the nature of the signal-transduction pathway. Thus, for ion channel opening, the delay is only milliseconds, while for DNA transcription, the delay may be in hours to days. This information is very useful while building the relationship between the concentration and effect for a drug. Cells in different tissues may have multiple receptors, each of which is specific for a particular ligand. For example, on the

myocardial cell, there are β -receptors, muscarinic receptors, and multiple ion channels. Functional groups present in the drug are important in forming intermolecular bonds with the target. However, the carbon skeleton of the drug also plays an important role in binding the drug to its target. Small changes in chemical structure can produce profound changes in potency. For example, codeine, which differs in structure from morphine only by methoxy group instead of a hydroxyl group, is ~ 1000 times less potent than morphine in its action on opioid pathway (Fig. 17.1).

Each drug may interact with multiple receptor subtypes to different extent. Few drugs may be absolutely specific for one receptor or subtype, but most drug candidates will have relative selectivity. Selectivity is the degree to which a drug acts on a given site relative to other sites. At higher concentrations, the same drug may interact with other targets (receptor subtypes or different targets) leading to undesirable effects.

Some of the major drug targets and signal-transduction mechanisms are briefly discussed below.

17.2.1 Ion Channels

Ion channels are membrane proteins, found virtually in all cells that are of crucial physiological importance. They are involved in electrical signaling in the heart and the nervous system, fluid secretions in the lung, gastrointestinal tract, kidney, and a variety of other key processes such as hormone secretions, the immune response, bone remodeling, and tumor cell proliferation [11,12]. Cellular functions in these organs require the passage of ions across the cell membrane. Because of this, drugs targeting ion channels can produce physiological changes in major body functions.

In excitable cells (nerve cells and various types of muscle cells), the orientation of the membrane potential is such that the cell interior is electrically negative against the outside at resting state. The orientation of the membrane potential is reversed for a brief period of time during excitation. This transient reversal is called the *action potential*. Its duration may vary from around 1 ms to several 100 ms depending on the cell type. This action potential rapidly spreads over the entire cell membrane, altering the functional state of the cell. Moreover, excitation of one cell often triggers excitation of neighboring cells by means of electrical or chemical coupling.

Ion channels are generally highly selective for the ions they conduct. More than 300 genes code for subunits of ion channels. Most ion channels can switch between

Figure 17.1 Structure of (a) codeine and (b) morphine. Structure determines interaction with the receptor.

open, closed, and inactivated states. Ion channels are classified by the principal ion they carry (sodium, Na^+ ; potassium, K^+ ; calcium, Ca^{2+} ; and chloride, Cl^-) and the mechanism by which they are opened and closed. Ion channels can be categorized as follows:

1. *Ligand-Gated Channels*. These channels either open or close in response to ligand binding. For example, nicotinic acetylcholine receptors allow Na^+ ions into the cell in response to acetylcholine.
2. *Voltage-Gated Channels*. The conductance of these channels is regulated by changes in voltage across the plasma membrane. Local anesthetics block the conductance of Na^+ ions through voltage-gated sodium channels in neurons that transmit pain information from the periphery to the central nervous system and hence the pain perception.

Ion channels are multisubunit proteins, with each subunit predicted to span the plasma membrane multiple times. Symmetrical association of the subunits allows each to form a segment of the channel pore and to cooperatively control channel opening and closing. The ligand-binding domain can be extracellular, within the channel, or intracellular. Agonists may bind to a particular subunit that may be represented more than once in the assembled multimer (e.g., nicotinic acetylcholine receptor) or may be conferred to a single subunit of the assembled channel [e.g., sulfonylurea receptor that associates with the K^+ channels to regulate the ATP-dependent K^+ channels (K_{ATP})]. Sulfonylureas bind to the SUR1 subunits and block the ATP-sensitive potassium channels. Role of K_{ATP} in insulin release is shown in Fig. 17.2. Increase in blood glucose after a meal raises intracellular ATP concentration in the pancreatic β -cell and results in closure of K_{ATP} channels. It results in inhibition of potassium efflux and depolarization of the plasma membrane, thereby leading to increase in influx of calcium through voltage-sensitive calcium channels. Rise in $[\text{Ca}^{2+}]_i$ triggers exocytosis of insulin granules, thereby stimulating insulin secretion [13]. Openers of the same channel (K_{ATP}) may lead to membrane hyperpolarization, resulting in vascular smooth muscle relaxation (e.g., minoxidil).

Figure 17.2 ATP-sensitive K^+ (K_{ATP}) channel as a major regulator of insulin secretion. *Source:* Adapted from Ref. 13.

17.2.2 G-Protein-Coupled Receptors

GPCRs are the target for more than 50% of the drugs currently in the market [14]. These proteins are expressed at the extracellular surface of the cell membrane, traverse the membrane, and possess intracellular regions that activate G-proteins. G-proteins are called so due to their interaction with the guanine nucleotides, guanosine triphosphate (GTP), and GDP. GPCRs bind to a wide variety of molecules, including biogenic amines, peptides, glycoproteins, lipids, nucleotides, ions, and proteases. They are involved in diverse biological functions, including the senses of smell, taste, and sight, and regulation of appetite, digestion, blood pressure, reproduction, inflammation, and so on [15,16]. GPCRs can be found in the central nervous system and in the periphery. Their role in different tissues may be different, although the second messengers that result from the initial activation are probably similar (e.g., muscarinic acetylcholine receptors, α - and β -adrenoceptors, serotonin receptors, and histaminergic receptors).

All GPCRs have seven transmembrane regions within a single polypeptide chain. In the resting state, G-proteins exist as attached $\alpha\beta\gamma$ trimer, with GDP occupying the site of the α -subunit. When the GPCR is occupied by an agonist molecule in the extracellular domain, a conformational change occurs and the G-protein binds to cytoplasmic domain of the receptor. Association of the $\alpha\beta\gamma$ trimer with the receptor causes the bound GDP to dissociate and to be replaced with GTP, which in turn causes dissociation of α -GTP unit from the $\beta\gamma$ subunit. The α -GTP is the active form of the G-protein, which diffuses in the membrane and can interact with a number of different effectors. These effectors include adenylyl cyclase, phospholipase C, ion channels, and other classes of proteins. Signals mediated by G-proteins are terminated by the hydrolysis of GTP to GDP through the GTPase activity of the α -subunit. Different G α -protein isoforms have now been identified, each of which have unique effects on their targets. A few of these G-proteins include G-stimulatory (Gs), G-inhibitory (Gi), Gq, G0, and G12/13. The major role of the G-protein is to activate the production of second messengers through different pathways. The key G-protein-coupled effector systems are briefly discussed below.

17.2.2.1 The Adenylate Cyclase/cAMP System. The cyclic 3',5'-adenosine monophosphate (cAMP) is the nucleotide synthesized within the cell from ATP by the action of adenylate cyclase. It is produced continually and inactivated by hydrolysis to 5'-AMP by the action of phosphodiesterases. The cAMP in turn activates various protein kinases. These enzymes catalyze the phosphorylation of serine and threonine residues in different cellular proteins and thereby regulate cell function. The regulatory effects of cAMP on cellular function are diverse (e.g., energy metabolism, cell division, cell differentiation, ion transport, changes in neuronal excitability, and contraction of smooth muscles).

17.2.2.2 Phospholipase C/Inositol Phosphate System. Activation of phospholipase C, a membrane bound enzyme, hydrolyzes a membrane phospholipid, phosphatidylinositol-4,5-bisphosphate (PIP₂) to generate inositol-1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG). IP₃ binds to receptors on Ca²⁺ channels in the endoplasmic reticulum, triggering the release of calcium. Calcium can bind to calmodulin and the resulting Ca²⁺-calmodulin complex can further bind to intracellular enzymes such as Ca²⁺-calmodulin-dependent protein kinases. Increase in intracellular Ca²⁺ is the major effector mechanism by which various neurotransmitters, hormones,

and drugs promote contraction of the smooth muscle. The other product, DAG, is hydrophobic, which remains associated with the membrane, activates protein kinase C, and controls phosphorylation of serine and threonine residues of a variety of intracellular proteins. Protein phosphorylation is the key mechanism through which many physiological mediators and drugs produce their effects. For example, release of hormones from many endocrine glands, increase or decrease in the neurotransmitter release and in neuronal excitability, and contraction or relaxation of smooth muscle. The role of GPCRs in regulating enzymes and ion channels is shown in Fig. 17.3.

The receptor-linked G-proteins can also activate phospholipase A₂, which releases arachidonic acid and thus initiates synthesis of prostaglandins and related eicosanoid mediators. The receptor-linked G-proteins are involved in direct regulation of the ion channels. For example, muscarinic acetylcholine receptors are known to enhance K⁺ permeability, thus hyperpolarizing the cells and inhibiting electrical activity.

17.2.3 Tyrosine Kinase and Guanylate-Cyclase-Linked Receptors

There are two classes of tyrosine kinases. Receptor tyrosine kinases (RTKs) are type I transmembrane proteins possessing an N-terminal extracellular domain, which can bind to an activating ligand, a single transmembrane domain, and a C-terminal cytoplasmic domain that includes the catalytic domain. Nonreceptor tyrosine kinases lack a transmembrane domain; most are soluble intracellular proteins and activated in a similar manner as RTKs.

The RTKs catalyze the transfer of phosphate from ATP to hydroxyl groups of tyrosine on target proteins. RTKs play an important role in the control of most fundamental cellular processes, including cell proliferation, cell cycle progression, metabolic homeostasis, transcriptional activation, neural transmission, and aging. They mediate signaling by insulin and a variety of growth factors such as epidermal growth factor (EGF), platelet-derived growth factor (PGF), and nerve growth factor. When activated, these receptors dimerize followed by autophosphorylation of tyrosine residues in the cytoplasmic domain. The phosphorylated tyrosine residues serve as the binding site for the SH2 domains of a variety of intracellular proteins, thereby

Figure 17.3 G-protein-coupled receptors and main signaling pathways. AC, adenylate cyclase; PLC, phospholipase C; PLA₂, phospholipase A₂; I, inositol triphosphate; DAG, diacylglycerol. Source: Adapted from Ref. 17.

allowing control of many cell functions. Important signaling pathways activated by RTKs include Ras/extracellular signal-regulated kinase mitogen-activated protein (ERK MAP) kinase cascade and PI-3 kinase pathway [18,19]. Examples of tyrosine kinase inhibitors approved recently are imatinib and dasatinib in chronic myeloid leukemia, gefitinib in lung cancer, and lapatinib in breast cancer.

Guanylate cyclase, a membrane bound enzyme, is similar in its regulation to the tyrosine kinase family. Receptors linked to guanylate cyclase, once activated lead to the production of 3',5'-cyclic guanosine monophosphate (cGMP) from GTP. Natriuretic peptide, a hormone secreted from the ventricles in response to volume overload, acts via receptor guanylate cyclase.

17.2.4 Intracellular and Nuclear Receptors

Nuclear receptors that mediate the actions of classical hormones can be divided into two groups. Type I nuclear receptors include the steroid hormone receptors (e.g., androgen receptor, estrogen receptor (ER), glucocorticoid receptor, mineralocorticoid receptor, and progesterone receptor). When the receptor is not bound to a ligand, type I nuclear receptors are located in the cytoplasm associated with molecular chaperons (heat shock proteins) that maintain the receptors in a conformation that allows for ligand binding but not DNA binding. On hormone binding, type I nuclear receptors undergo a conformational change that results in the release of components of the chaperone complex, exposure of a nuclear localization sequence, and translocation to the nucleus where they associate with chromatin and regulate gene transcription [20].

The type II nuclear receptors include thyroid hormone receptor, vitamin D receptor, and retinoic acid receptor (RAR) and retinoid X receptor. In contrast to the type I nuclear receptors, the type II nuclear receptors reside in the nucleus, constitutively bound to DNA, and usually act as transcriptional repressors in the absence of hormone. Another class of nuclear receptors is called *orphan receptors*, for which regulatory ligands are still unknown (e.g., hepatocyte nuclear factor 4, HNF4 α) [20]. Because of the essential role played by nuclear receptors in many aspects of mammalian development, metabolism, and physiology, dysfunction of signaling controlled by these receptors is associated with reproductive, proliferative, and metabolic diseases. For example, tamoxifen used in the treatment of breast cancer acts via ER α , retinoic acid used in acute promyelocytic leukemia acts via RAR α receptors, and thiazolidinediones targeted in type II diabetes act via peroxisome proliferator-activated (PPAR γ) receptors [21].

17.2.5 Desensitization or Tachyphylaxis

Desensitization or tachyphylaxis refers to a spontaneous decline in the response to a continuous or repeated application of agonist [7] and may be elucidated to prevent potential damage to the cell (e.g., high concentrations of calcium may initiate cell death). When repeated administration of a drug results in diminished response, the phenomenon is called *desensitization* or *tachyphylaxis*. This may develop in the course of a few minutes. The term *tolerance* is conventionally used to describe a more gradual decrease in response to a drug, taking days or weeks to develop. The desensitization of receptors may be due to change in receptor morphology, exhaustion of mediators, or loss of receptors (downregulation). Examples include morphine, ephedrine, and amphetamine.

17.2.6 Actions of Drugs Not Mediated by Receptors

Some drugs do not interact with macromolecular receptors to produce effect. For example, antacids such as sodium bicarbonate chemically neutralize gastric acid and reduce the symptoms of heart burn. Mannitol, an osmotic diuretic, is not reabsorbed in the renal tubule and increases the osmolarity of the glomerular filtrate, facilitating excretion of water. Cholestyramine resin, a lipid-lowering drug, sequesters bile acids in the intestine and decreases the absorption of exogenous cholesterol.

17.3 DRUG–RECEPTOR INTERACTIONS

17.3.1 Agonists

Ligands that bind to the receptor and alter the receptor state resulting in a biological response are called *agonists*. When bound by an agonist, a typical receptor is more likely to be in its active conformation. Agonists may act by combining either with the same site as the endogenous agonist (primary or orthosteric site) or, less commonly, with a different region of the receptor macromolecule (allosteric or allotropic site). A full agonist has a strong affinity for its receptor and good efficacy. For example, phenylephrine is an agonist at α_1 -adrenergic receptors. On binding to α_1 -adrenoceptors on the vascular smooth muscle membranes, phenylephrine mobilizes intracellular calcium causing contraction of actin and myosin filaments, thereby decreasing the diameter of the blood vessel. Some agonists (e.g., glutamate) may only be effective in the presence of another ligand (e.g., glycine in the case of glutamate) that binds to a different site on the receptor. In such cases, glutamate is referred to as the *primary agonist* and glycine as a *coagonist* [7]. A typical relationship between response and agonist concentration is shown in Fig. 17.4.

As it can be seen in Fig. 17.4, the response increases with increase in agonist concentration. Up to a certain concentration, the response is directly proportional to the concentration, but at higher concentrations, the curve becomes asymptotic. This is the result of a capacity-limited, saturable process. To accommodate a wide range of concentrations, the relationship between effect and concentration is usually plotted on a semilog scale, which transforms the plot to a sigmoidal shape. When developing concentration–effect relationship, one may consider using free (not protein bound) drug

Figure 17.4 Concentration–effect relationship for an agonist.

concentrations since according to the free drug hypothesis, the free drug concentration at the site of action is the species that drives pharmacological activity.

17.3.2 Spare Receptors

Many agonists are able to produce maximal response without fully occupying all the receptors. Thus, not all the receptors in the tissue are required to achieve maximal response with some high efficacy agonists. Agonists may elicit the same maximal response, albeit at different receptor occupancies. This has been demonstrated experimentally by Furchgott (1966) and others that even with irreversible inactivation of some receptors, an agonist is still able to produce maximal response [7,22]. For example, at the skeletal neuromuscular junction, activation of <1% of receptors elicits an action potential and maximal contraction of muscle fibers. Hence, the neurotransmitter acetylcholine produces a maximum response by activating only a small proportion of receptors in the receptor pool.

17.3.3 Partial Agonists

A partial agonist cannot elicit as large an effect (even when applied at high concentrations to occupy all available receptors) as another agonist acting through the same receptors in the same tissue resulting in lower efficacy compared to full agonists (Fig. 17.5 [7]). Inability to produce a maximal response may be due to inability to convert the occupied receptors to an active form. For agents acting on opioid receptors, morphine and fentanyl are full agonists of the opioid receptors capable of inducing strong analgesia, while buprenorphine and pentazocine are partial agonists.

17.3.4 Inverse Agonists

Inverse agonists bind to receptors and reduce the fraction of receptors in active conformation [7]. This can occur when receptors exist both in active (R^*) and inactive

Figure 17.5 Different types of agonist action on receptors.

conformation in the absence of agonists:

An inverse agonist L, combines preferentially with inactive receptors, it will reduce the fraction in the active state:

An inverse agonist may combine either with the same site as a conventional agonist or with a different site on the receptor macromolecule. Conventional agonists increase receptor activity, whereas inverse agonists reduce it. For example, antiallergic H_1 receptor antagonists, cetirizine, loratadine, and epinastine, may act through inverse agonism (i.e., stabilization of inactive confirmation of the histamine H_1 receptor) [23]. This has also been reported for several systems, including benzodiazepine and cannabinoid (CB) receptors.

17.3.5 Affinity

Affinity can be defined as the extent of binding to receptors at any given drug concentration. Drugs that have high affinity require fewer drug molecules to produce a certain degree of binding. However, affinity is not synonymous with efficacy, that is, an antagonist may have affinity but no efficacy. Affinity is usually represented as the reciprocal of the dissociation constant of the ligand–receptor complex (k_{-1}/k_1 , where k_{-1} is the first-order rate constant of dissociation of ligand from the receptor and k_1 is the second-order rate constant of association of the ligand to the receptor). Refer to Section 17.6 for a schematic derivation of a receptor–ligand interaction.

17.3.6 Efficacy and Potency

Efficacy and potency can be determined by graded concentration–effect curves. The ability to produce a response is termed *efficacy* (intrinsic activity). Efficacy is a molecule-related property, and different molecules may have different capabilities to produce a physiological response. It is dependent on the number of drug–receptor complexes formed and the efficiency of subsequent transduction pathways. A drug with greater efficacy may be more therapeutically beneficial than one that is more potent (Fig. 17.6). Potency is an expression of the activity of a drug, in terms of the concentration or amount needed to produce a defined effect (e.g., EC_{50}). EC_{50} can be defined as the concentration of an agonist that produces 50% of its maximal possible effect. $E_{\max}$ is the maximal response produced by the drug. The agonist activities of drugs to induce a response can be categorized by comparing EC_{50} and $E_{\max}$. The maximum response depends on efficacy. If an agonist has high efficacy, it does not necessarily mean that it will display high potency and vice versa.

17.3.7 Antagonist

A drug that reduces the action of another drug, generally an agonist, is referred to as *antagonist*. Antagonism may be competitive or noncompetitive. In competitive antagonism, the antagonist competes with the agonist for the binding site on the receptor.

Figure 17.6 Concentration–effect relationship for two agents, A and B. A is more potent than B. A and B are equivalent in efficacy (e.g., pain relief). B is preferable than A due to its separation from concentration–effect relationship for side effect (e.g., motor deficit).

Figure 17.7 Effect of antagonist on agonist concentration–effect relationship.

For example, the antihypertensive drug prazosin competes with the endogenous ligand, norepinephrine at α_1 -adrenergic receptors, thereby reducing blood pressure. Plotting the effect of the competitive antagonist shifts the agonist dose–response curve to the right. Noncompetitive antagonists can bind to either the active site or an allosteric site of the receptor. A characteristic difference between competitive and noncompetitive antagonists is that competitive antagonists reduce agonist potency, whereas noncompetitive antagonists reduce agonist efficacy (Fig. 17.7). For example, cyclothiazide is a noncompetitive antagonist of mGluR1 receptor (metabotropic glutamate receptors) by interacting at an allosteric site of the receptor [24]. In the case of physiological antagonism, the antagonist binds to a different receptor altogether. For example, histamine binds to H_1 receptors on bronchial smooth muscle, causing contraction and narrowing of bronchus, while epinephrine acts as an agonist at β_2 -adrenoceptors on bronchial smooth muscle, causing relaxation.

In the following section, we have discussed how drug effects are measured at the molecular/physiological level. All these receptors, ion channels, and so on are part of systems such as organs. Efforts are being made recently to understand the progression of disease and drug effect on these systems. This understanding helps in identifying suitable entities in the system, which is more representative of the disease and hence more helpful in understanding the effect of a drug.

17.4 BIOMARKERS

The elucidation of the human genome and advances in proteome sciences have led to the identification of numerous potential novel pharmacological targets. Recent statistics in the drug discovery and development space, however, indicate that the failure rate of novel molecular entities (NMEs) is very high, with about 80% attrition occurring in clinical development [25]. The major factor responsible for this attrition is lack of efficacy and/or unacceptable safety. Most novel mechanisms turn out to be pharmacologically not viable as tested in proof-of-concept trials. Also, large epidemiological studies that characterize patient populations with respect to disease and its progression, as well as the role of pharmacologic targets in disease are lagging behind compared to the pace of new target identification at the molecular level. In order for drug discovery/development to be more successful, one needs to have the following:

1. increased probability of success of the unprecedented targets selected,
2. optimized validation of new targets,
3. selecting the best molecules, and
4. accelerating their advancement toward proof of concept in patients.

To stop prosecuting mechanisms or molecules that show insufficient early evidence of biological benefit is equally important, such that resources can be focused on more promising ones.

In a white paper published by the Food and Drug Administration (FDA) in 2004, titled “Innovation or Stagnation,” the need for “a new product development toolkit” was emphasized. In order to improve the translation from laboratory concept to commercialized product, new powerful scientific and technological advances were recommended comprising *in silico* or animal models and biomarkers for safety, efficacy, and new clinical evaluation techniques. Ideally, biomarker research begins during the discovery phase, with strategic application during early clinical development and continued implementation through late stage development.

The Biomarkers Working Group (representation from the FDA, National Institute of Health (NIH), academia, and drug industry) arrived at a consensus definition of a biomarker as “a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention” [26]. Biomarkers may be of greatest value in early stages of the development of a drug to establish proof of concept in both *in vitro* and *in vivo* models.

A clinical end point is defined as a characteristic or variable that reflects how a patient feels, functions, or survives. Clinical end points reflect desired effects of

therapeutic intervention and are the most credible response measurements in clinical studies [26]. “A surrogate end point” is defined as a biomarker that is intended to substitute for a clinical end point. A surrogate is expected to predict clinical benefit (or harm or lack of benefit) based on epidemiologic, therapeutic, pathophysiologic, or other scientific evidence [26]. The actual clinical outcome has been classically measured as morbidity/mortality parameters or how a patient is functioning and feeling. Relatively few biomarkers have qualified for the evidentiary status of a surrogate end point. The availability of predictive biomarkers is a key factor in translational approaches in drug discovery and development. Their strategic application has utility at several stages, for example,

- demonstrate proof of target engagement in nonclinical species,
- facilitate design and/or selection of lead compounds,
- predict toxicity in nonclinical species,
- selection of first-in-human (FIH) dose,
- design of early clinical trial,
- enable go-no-go decisions toward expensive late phase trials,
- choice of appropriate patient populations,
- demonstrate proof of concept in disease in humans,
- estimation of therapeutic index, and
- regulatory approvals based on surrogate clinical end points.

17.4.1 Types of Biomarkers

17.4.1.1 Proximal and Distal Biomarkers. Biomarkers employed during early clinical development serve to demonstrate target engagement and are termed as *proximal biomarkers*. They inform on the concentration–response relationship between drug PK and modulation of a selected pharmacological response, such as receptor occupancy, *ex vivo* inhibition of an inflammatory marker, kinase inhibition, change in mRNA, and target enzyme activity. Selected examples of proximal biomarkers used in proof-of-pharmacology assessment of novel entities are listed in Table 17.1 [27].

Disease-related biomarkers, termed as *distal biomarkers*, are employed at the same time or somewhat later in the clinical development to demonstrate effect of target modulation by the drug on disease pathophysiology. These biomarkers assess drug’s effect on a disease, are linked to clinical benefits, and thus have the potential of qualifying as surrogate end points. Examples are blood pressure reduction, insulin and blood glucose modulation, cholesterol and HDL modulation, and ACR20 score in rheumatoid arthritis. For additional examples, refer to Table 17.1 [27].

17.4.1.2 Technology-Based Classification of Biomarkers. Depending on the biological target and therapeutic area, a variety of pathway- or disease-related biomarkers have been proposed. Roughly, they can be classified as “-omics”-based (genomic, proteomic, and metabolomic), activity-based, or imaging-based approaches.

TABLE 17.1 Proximal and Distal Biomarkers in Different Disease Areas

Therapeutic Area	Proximal Biomarker	Distal Biomarker	Examples	References
Diabetes	Dipeptidyl peptidase-4 (DPP-4) Glucagon-like peptide-1 (GLP-1) Adiponectin Urinary glucose excretion	Blood glucose HbA1c	Sitagliptin, PPAR agonists, Dapagliflozin	27,35,36
Obesity	Positron emission tomography for targets NYP-5 and CB-1	Body weight	MK-0557 MK-9470	27,37
Cardiovascular: Hypertension and Atherosclerosis	C-reactive protein, HDL, LDL, adiponectin, Serum thromboxane B ₂ levels, Plasma renin activity	Blood pressure	Statins, Aspirin, BAY-10-6734	38–40
Immunology: Rheumatoid arthritis	Tumor necrosis factor α (TNF- α), Multiple cytokines, MCP-1-induced chemotaxis in synovial fluid	ACR20 score	Infliximab	41
Alzheimer's disease	β -Amyloid peptide in CSF and plasma	Cognitive score	LY450139	42
Multiple sclerosis	Lymphocyte count	Aggregate relapse rate and physical disability	Fingolimod	43

17.4.1.2.1 “-omics”-Based Biomarkers. Genomics provides a measure of the transcribed genome (transcriptome). Pharmacogenomics has evolved as one of the main applications of biomarker discovery and has delivered decision-making biomarkers. Examples are provided in Table 17.2. Translatability has been achieved by profiling effects of drug treatment on gene expression in cell/tissue culture or *in vivo* in animals and clustering certain genes/pathways for further validation in human trials. Standardization of gene expression microarrays or gene chip technologies has had a tremendous impact in facilitating the use of this approach in biomarker discovery and development. Genomics is different from genetics in that the latter is an analysis of genome in normal

TABLE 17.2 Examples of Genomic Biomarkers

Drug	Indication	Biomarker
Imatinib mesylate	Stomach cancer	C-KIT expression
Boceprevir	Hepatitis C virus	il28B
Cetuximab	Colorectal cancer	EGFR expression
Cetuximab	Colorectal cancer	KRAS
Maraviroc	HIV	CCR5
Trastuzumab	Breast cancer	Her2/neu expression
Irinotecan	Colon rectum cancer	UGT1A1 variant

or disease state, including identification of genetic variants (insertion, deletion, amplification, single nucleotide polymorphisms, etc.). The correlation of genetic variation in disease state has the potential to provide mechanisms of drug action and select appropriate patient population. One of the earliest examples was the enrollment of breast cancer patients positive for HER2 amplification for treatment with trastuzumab [28]. Another genomic application for patient selection/labeling is that of polymorphic drug metabolizing enzymes CYP2D6, CYP2C9, and CYP2C19. Depending on the CYP allele, patients may be extensive or poor metabolizers of drugs that are primarily metabolized by these enzymes, potentially leading to a significant variability in drug exposure. The US FDA Web site provides a table of pharmacogenomic biomarkers in drug labels and is available at www.fda.gov/drugs/scienceresearch/researchareas/pharmacogenetics. There is increasing evidence that pharmacogenomics can play an important role in identifying responders and nonresponders to medications, avoiding adverse events, and optimizing drug dose. Drug labels containing information on genomic biomarkers describe the following:

- drug exposure and clinical response variability,
- risk for adverse events,
- genotype-dependent dosing,
- mechanisms of drug action, and
- polymorphic target and disposition genes.

Using gene expression arrays (e.g., Affymetrix) as PD biomarkers has certain limitations [29]. In a rat model of rheumatoid arthritis, methylprednisolone was administered exogenously to normal and diseased rats and cytokine gene expression changes were monitored. Normal rats were shown to exhibit circadian rhythms in gene expression in the liver and muscle that peaked at a time different from the disease rats. After a single dose of methylprednisolone, the gene expression may show a biphasic response and the change in gene expression may not be predictive of that after chronic administration.

Consistency in gene expression across different laboratories is also a challenging issue, so is the influence of environmental factors. Owing to the complexity and variability of gene expression profiles, combination with other biomarkers is often necessary.

Proteomics may be considered a more direct approach to the discovery of mechanistic/functional biomarkers of drug action. The proteome is more complex than the genome and transcriptome and reflects protein abundance, posttranslational modifications, localization in cells, and interaction with other macromolecules. Although this complexity defines the biological homeostasis, it also makes it difficult to identify protein biomarkers and establish robust/reproducible assays that quantify drug-related changes. Defined panels of candidate protein biomarkers can be analyzed via high throughput technologies, such as protein arrays and multiple-reaction monitoring mass spectrometry. ELISA-based protein immunoassays are still considered the gold standard. In Alzheimer's disease, the levels of disease-related CSF biomarkers such as amyloid β -peptide 1-42 (Ab42), tau, and phosphorylated tau (p-tau) may increase diagnostic accuracy. Good correlation is observed in the levels of CSF biomarkers and amyloid imaging by PET.

Metabolomics encompasses the effect of drug treatment on small-molecule endogenous biochemicals, as a result of activation or inhibition of their biosynthetic and/or

disposition pathways. Many of these biomarkers form a part of standard clinical chemistry panels and are applied in the detection of organ-based toxicity. Glucose and cholesterol are examples of metabolomic biomarkers that have been successfully applied in the development and approval of antidiabetic and antiatherosclerotic therapies, respectively. Together, the genetic, genomic, proteomic, and metabolomic approaches constitute “molecular profiling.”

17.4.1.2.2 Activity-Based Biomarkers. Pharmacological target-based activity assays represent the most direct assessment of functional activity of new drugs. Given that plasma remains the most accessible biological fluid during clinical development, *ex vivo* whole-blood or plasma biomarkers are highly desirable. *Ex vivo* whole-blood CD11b, tumor necrosis factor α (TNF- α), or suitable interleukin (IL) assays as inflammatory biomarkers (Table 17.1). Depending on drug distribution, and anticipated site of action, tissue fluids such as CSF and synovial fluid are sampled or tissue biopsies such as liver or tumor are accessed for analysis of biomarkers.

17.4.1.2.3 Imaging-Based Biomarkers. Molecular imaging refers to noninvasive or minimally invasive technologies for visualizing, characterizing, and quantifying anatomical structures and physiological processes at the cellular and subcellular levels, with exquisite spatial, temporal, and biochemical resolution *in situ* and *in vivo* [30]. PET, single photon emission computed tomography (SPECT), computer tomography (CT), magnetic resonance imaging (MRI), ultrasound (US), and optical imaging are used for biomarker measurement. These techniques differ in terms of the mechanisms used to generate images, imaging probe characteristics, and their resolution and sensitivity. The most commonly used imaging approach is nuclear imaging that visualizes radiotracers interacting with protein targets located intracellularly or on the cell surface. PET uses ^{11}C and ^{18}F , while SPECT uses ^{123}I as radionuclides. They are used for tracking the drug itself (small molecule or protein), imaging the pharmacological target, or monitoring key biochemical and physiological processes. There are a few examples in which imaging techniques have been used to support drug registration (oncology, neurology, cardiovascular, and musculoskeletal). There are other examples in which these techniques have been used to make early go-no-go decisions, in the CNS and obesity area from Merck laboratories: for example, CB-1 receptor inverse agonist MK-9470 and neuropeptide receptor Y5 (NPY5) receptor antagonist MK-0557 [27].

In order to select appropriate biomarkers and incorporate them into the design of clinical trials, it is important to be aware of the wide variation in the turnover rates of biomarkers. For example, electrical signals, neurotransmitters, and chemical signals turn over in seconds; hormones, enzymes, and mRNA in several hours; cells and tissues in weeks; organs such as bone in 10 years; and human life span in 100 years.

17.4.2 Biomarker in Different Stages of Drug Development

In early research, the selection of biomarkers to support mechanistic studies in cell-based and animal models should depend on their translation to human samples. Biomarkers to investigate target engagement and its efficacy on disease status should be incorporated in early clinical trials, as it helps assess the possibility of success

in large-scale clinical trials by relating clinical data to preclinical test systems and by determining whether drug is affecting the molecular target and whether it is translating into therapeutic benefit. The use of biomarkers in clinical development can be categorized into four types and show increasing decision-making and regulatory application:

1. *Exploratory*. Supported by *in vitro* and preclinical data but with no consistent information regarding their link to clinical outcome in humans.
2. *Demonstrated (Probable Valid)*. With sufficient preclinical sensitivity and specificity and are linked to a clinical outcome but without reproducible evidence.
3. *Characterized*. Both preclinical and clinical validation, as listed in “1” and “2” above, as well as show reproducibility in more than one prospective clinical study.
4. *Surrogate*. Biomarkers that demonstrate utility as a substitute for a clinical end point. This scheme shows the increasing decision-making and regulatory application.

Biomarker qualification represents the progressive transition from exploratory stage to surrogacy. Biomarkers may also enter qualification stage from general medical practice. For example, low density lipoprotein (LDL) cholesterol was in general medical use before its role in drug development. Biomarkers may also be “disqualified” if evidence does not support their intended use. For example, suppression of intermittent ventricular tachyarrhythmia as a marker of reduction in ventricular arrhythmia and mortality due to myocardial infarction was disqualified as a biomarker because a controlled cardiac arrhythmia suppression trial demonstrated that mortality was increased by antiarrhythmic treatment following an infarction.

The process of biomarker qualification gauges the evidentiary status from exploratory application to prediction of clinical outcome. A consensual framework is required to define surrogacy due to the current lack of consistent evidentiary standards, as identified in FDA’s critical path initiative. Lathia *et al.* [31] have reviewed the types of evidence supporting or not supporting certain surrogate end points. A complication in selecting “a” surrogate end point is that most outcomes are multidimensional, thus crucial information such as safety issues can be missed by employing a single measure. Thus, based on preclinical information, it is better to use multiple biomarkers to evaluate efficacy and safety during development of drug candidates. FDA-NIH consensus conference on biomarkers (1999), FDA Critical Path Initiative (2004) [32], and European Medical Agency Roadmap (EMA, 2010) [33] have advocated different biomarker strategies. The biomarker consortium, a public–private collaboration was launched in 2006. The role of consortia (among regulatory, industrial, academic, and government representatives) in biomarker development and application enables collaborative pooling of (precompetitive) data and benefits all participants by increasing the availability of validated and qualified biomarkers. In order to promote qualification and regulatory acceptance of biomarkers, research data and results are made broadly available to public to help speed disease-specific research.

Successful application of PK-PD modeling in drug discovery and development depends on a thorough understanding of the following:

1. the disposition of the molecular entity being developed, including its Absorption, Distribution, Metabolism, Excretion (ADME) characteristics in preclinical species and human;
2. the pharmacology of target modulation, including assessment of potency and efficacy in *in vitro* binding and functional assays and *in vivo* concentration–response relationships in preclinical species and human; and
3. the disease pathophysiology, including a cause–effect relation between the target and disease and effect of drug on disease or surrogate end points

Therefore, biomarkers play a major role in discovery of target, evaluation of drug candidates in preclinical models, early- and late-phase clinical development, and approval from federal agency with the help of PK-PD modeling incorporated in clinical trial simulations, as exemplified in a recent Pfizer article by Morgan *et al.* [34].

17.5 MATHEMATICAL MODELS IN PHARMACODYNAMICS

PK-PD modeling has been gaining its importance in both drug discovery and development stage in recent years. In one of their reports in 2004, Donald Stanski, the scientific advisor to the Center for Drug Evaluation and Research, FDA, stated that “the latest buzzwords at the FDA are model-based drug development” [44]. The primary objective of PK-PD modeling is to characterize drug-specific parameters such as $E_{\max}$ and EC_{50} , as defined in Section 17.2, as well as system-specific factors such as production (k_{in}) and dissipation (k_{out}) rates of PD responses, k_{e0} , tau (τ), as has been defined in this section. The effect of a drug that depends on its interaction with the receptor is usually known as *primary effect*. The primary effect causes the physiological system and its various components to respond, which translates to clinical response [45]. In preclinical studies, PK-PD modeling is often used to estimate the FIH dose. Another application is the use of physiological modeling and allometry of PK/toxicokinetic data and extrapolation of the results from animals to human. In clinical settings, PK-PD modeling is used to interpret the dose–response data for single ascending dose (SAD) studies and decide doses for the dose escalation studies. This is primarily true where a single dose exhibits change in the PD biomarker. PK-PD modeling also has been used by the FDA to propose dose or dosage regimen(s) that were not originally recommended by the sponsors. A variety of mathematical models have been used to analyze different types of PD responses. There are two kinds of response. A graded or continuous response is a one where the response can be measured as a continuous function of dose, concentration, or time. These types of data have been typically modeled by deterministic models. Examples of such response data would be change in heart rate, temperature, and enzyme activity. The other type of response is known as *dichotomous response* and is either “all” or “none.” Stochastic models have been used to analyze this kind of data. In this section, we describe the different types of models typically used to describe dose–response or exposure–response data and encompass the basic model structure, PK-PD expectations from these types of models, determination of initial estimates of drug-specific and system parameters, and applications reported in

the literature. Additional complexities outside the scope of this discussion provided can be found in the References section.

17.6 CONCENTRATION-RESPONSE RELATIONSHIP

A drug must bind to its target in order to exert its PD effects. As discussed previously, these proteins may be enzymes, transporters, ion channels, or receptors. The most popular and appropriate model for receptor occupancy, proposed by Clark, is based on law of mass action. The law of mass action and small quantity of receptors lead to capacity limitation for most responses (Jusko WJ, State University of New York at Buffalo, New York, personal communication, March 2006). Below is a schematic representation of drug-receptor interaction:

Let us suppose that $[C]$ is the concentration of drug at the site of action, $[R]$ is the available concentration of receptors, R_{TOT} is total concentration of receptors (bound+free), and RC is the concentration of the drug-receptor complex. The primary assumption is that the effect is proportional to the drug-receptor concentration at a given time. At equilibrium, the rate of formation of the drug-receptor complex, governed by a second-order rate constant k_1 is equal to the rate of dissociation of the RC complex, governed by the first-order rate constant k_{-1} . Thus, the equation for the drug-receptor complex is as follows:

$$\frac{d[RC]}{dt} = k_1 \cdot [R] \cdot [C] - k_{-1} \cdot [RC] \quad (17.1)$$

At equilibrium when

$$\frac{d[RC]}{dt} = 0 \quad (17.2)$$

$$k_1 \cdot [R] \cdot [C] = k_{-1} \cdot [RC] \quad (17.3)$$

$$\frac{[R] \cdot [C]}{[RC]} = \frac{k_{-1}}{k_1} = K_D \quad (17.4)$$

where K_D is the equilibrium dissociation constant. A lower value of K_D indicates a poor dissociation of the drug-receptor complex translating into high affinity of the drug for a given receptor.

Solving for $[RC]$ yields

$$\frac{([R_{TOT}] - [RC]) \cdot [C]}{[RC]} = \frac{k_{-1}}{k_1} = K_D \quad (17.5)$$

Rearranging the above equation, one can arrive at

$$\frac{[RC]}{[R_{TOT}]} = \frac{[C]}{[C] + K_D} \quad (17.6)$$

Ariens [46] introduced the concept that effect is directly proportional to the concentration of the drug–receptor complex and the proportionality constant ε was called the *intrinsic activity of the agent*:

$$\varepsilon = \frac{[RC]}{E} \quad (17.7)$$

The maximal drug response occurs when all the receptors are occupied and thus,

$$\varepsilon = \frac{[R_{\text{Tot}}]}{E_{\text{max}}} \quad (17.8)$$

Substituting in Equation 17.6 yields the following equation:

$$E = \frac{E_{\text{max}} \cdot [C]}{[C] + K_D} \quad (17.9)$$

K_D , the affinity for the drug can be replaced by EC_{50} (or the potency) for the agent to yield Equation 17.10. EC_{50} is defined as the concentration of the drug that produces 50% of its maximum effect:

$$E = \frac{E_{\text{max}} \cdot [C]}{EC_{50} + [C]} \quad (17.10)$$

Thus, the binding of a drug to the receptor can translate to the clinical response E . In PD modeling, a drug bound to a receptor may either stimulate (S) or inhibit (I) a process as described by the following equations:

$$S = 1 + \frac{S_{\text{max}} \cdot [C]}{SC_{50} + [C]} \quad (17.11)$$

$$I = 1 + \frac{I_{\text{max}} \cdot [C]}{IC_{50} + [C]} \quad (17.12)$$

17.7 CLASSIFICATION OF MATHEMATICAL MODELS IN PHARMACODYNAMICS

Figure 17.8 depicts the classification of different types of models used to analyze PD data. The models have been described in details in the following sections.

17.7.1 Reversible Effect Models

This category refers to the type of responses that return to the baseline or predose (physiological) levels as the drug is eliminated from the system (e.g., inhibition or stimulation of synthesis or dissipation of response, cell trafficking, and enzyme induction), causing no permanent damage to the system.

Figure 17.8 Types of pharmacodynamic models.

17.7.1.1 Direct Effect Models. A direct effect is observed when the action of the drug on its target is so rapid that there is no delay observed between the PK and PD profiles, for example, vascular targets or very rapid turnover processes such as muscle activity. The basic expectation of these effects is depicted in Fig. 17.9a and b. Figure 17.9a represents PK (C vs t) and Fig. 17.9b depicts effects versus time. Equation 17.13 represents the PK and Equation 17.14 represents the PD:

$$C_P = \frac{D}{V} \cdot e^{-k_{el} \cdot t} \quad (17.13)$$

$$E = \frac{E_{\max} \cdot C}{EC_{50} + C} \quad (17.14)$$

At $C_{\max}$, the effect reaches a maximum of 100. As the drug is eliminated, the effect diminishes and reaches a minimum at a sufficiently low drug concentration.

Figure 17.9 PK/PD expectations in case of direct effects. (a) Monoexponential PK and (b) PD. $k_{el} = 0.4$ units, $V = 10$ units, $E_{\max} = 100$, $EC_{50} = 100$.

17.7.1.1.1 Linear Effect Concentration Model. The simplest relationship between effect and concentration is represented by the following equation:

$$E = m \cdot C \quad (17.15)$$

This equation indicates that effect is zero when there is no drug present in the body and it increases with slope “ m ” as the concentration of the drug in the body increases. A situation very similar to this could be the presence of baseline of effect (E_0), which is represented by Equation 17.16. At $C = 0$, the effect is E_0 . As the concentration increases, the effect increases linearly with a slope “ m .” “ m ” can be easily estimated from the slope of the effect versus concentration plot:

$$E = E_0 + m \cdot C \quad (17.16)$$

17.7.1.1.2 Log-Linear Effect Concentration Model. This model finds its application in cases where the concentration varies over a wide range and appears curvilinear when plotted without log transformation. On log transformation, the data appear linear and the slope “ m ” can be estimated easily as described above (Eq. 17.17). The main assumption of this model is that changes in drug concentration and effect are proportional to one another:

$$E = m \cdot \log C + E_0 \quad (17.17)$$

17.7.1.1.3 Simple and Sigmoid $E_{\max}$ Models. A simple $E_{\max}$ and sigmoid $E_{\max}$ model is depicted by Equations 17.18 and 17.19, respectively:

$$E = \frac{E_{\max} \cdot C}{EC_{50} + C} \quad (17.18)$$

$$E = \frac{E_{\max} \cdot C^\gamma}{EC_{50}^\gamma + C^\gamma} \quad (17.19)$$

$E_{\max}$ indicates the maximum response caused by the drug. EC_{50} is defined as the concentration of the drug, which produces half the maximal response. The PK-PD expectation is shown in Fig. 17.9. In sigmoid $E_{\max}$ model, a shape factor is added to the simple $E_{\max}$ to make the slope of the response steeper or shallower. Figure 17.10 depicts how the values for the shape factor, γ , affect the profile. This shape factor provides more flexibility to the function so that the function can orient itself according to the shape of the data.

17.7.1.2 Delayed Effect Models. A drug, after administration, may produce effects which may be delayed from the PK. The maximum effect does not occur at the same time as the maximum plasma concentration. This may be due to distributional delays, turnover of endogenous proteins, or signal transduction. In this type of data if the plasma concentrations from each time point are plotted with the effect at the corresponding time point, they do not produce a hyperbolic profile but produce hysteresis (Greek meaning, the state of being behind or late). Figure 17.11a shows a typical PK-PD expectation for a delayed effect. The PK profile peaks at 1 h and the response peaks

Figure 17.10 Effect of the values of γ on the profiles of a simple $E_{\max}$ model.

at 2 h. Thus, the PD response is delayed by 1 h. Figure 17.11b shows a prototypical hysteresis plot produced when concentration is plotted against effect in case of delayed effects. For the same concentration of 40 units, there are two effects, 95 and 105 units. This profile cannot be analyzed using simple $E_{\max}$ -type model to resolve estimates of drug efficacy/potency. To obtain accurate estimates of efficacy, the PK-PD model needs to incorporate a component that captures the delay. In this section, we have made an effort to identify different types of mechanistic and empirical approaches, which account for these delays in drug response.

17.7.1.2.1 Biophase Model or Link Model. Biophase or link model has been applied to data where drug distribution to the site of action is assumed to be the rate-limiting factor for effect to occur. The term *biophase* was first coined by Furchgott [47]. This modeling approach was proposed and popularized by Sheiner *et al.* [48] for drugs showing delay in response. In their publication, Sheiner *et al.* included a hypothetical delay compartment to account for the disconnection observed in the PK and PD of the compound.

Figure 17.11 (a) Typical PK-PD expectation for a delayed PD effect and (b) hysteresis after plotting concentration with effect.

Figure 17.12 Biophase/link model.

The structure of the model is depicted in Fig. 17.12. C_P is the concentration of drug in plasma and C_e is the concentration of drug in the hypothetical effect compartment. Drug enters plasma by “input” and is eliminated by “elimination.” It also distributes to a hypothetical effect compartment by the rate constant k_{pe} and this distribution causes the delay for the observed effect. The basic assumption of this model is that the hypothetical effect compartment does not alter the PK of the drug. The plasma PK parameters are fixed. The rate constants k_{pe} and k_{e0} are assumed to be the same (k_{e0}) due to lack of identifiability. Thus, k_{e0} is defined as the rate constant causing distribution of drug to the hypothetical effect compartment and thus causing delay. An $E_{\max}$ model is then used to describe the effect versus time profile and C_P in the $E_{\max}$ equation is replaced by C_e , as shown in the following equations:

$$\frac{dC_e}{dt} = k_{e0} \cdot C_P - k_{e0} \cdot C_e \quad (17.20)$$

$$E = \frac{E_{\max} \cdot C_e}{EC_{50} + C_e} \quad (17.21)$$

The biophase/link model has been widely used in the literature to model PK-PD relationship of drugs showing delays in effect [49–51]. A nice example of using a biophase model to account for delay of electroencephalography (EEG) effect by midazolam, when using arterial sampling, was demonstrated by Tuk *et al.* [52]. Arterial data showed anticlockwise hysteresis but no hysteresis was observed with the use of venous concentrations.

SIGNATURE PROFILES. Figure 17.13 shows the simulations performed on a typical biophase or link model. The following parameter values were used to perform the simulations:

$$k_{el}=0.4, k_{e0}=0.5, E_{\max}=100, EC_{50}=100, V=1, \text{dose : } 10, 100, 1000, 10,000 \text{ units}$$

As one would expect, the peak effect occurs at a later time than that of $C_{\max}$. $T_{\max}$ of the effect is the same for all doses. Decreases in values of k_{e0} will produce more delay. On the basis of the values of k_{e0} , the effect compartment may produce flip-flop kinetics.

Figure 17.13 Signature profiles of plasma compartment, effect compartment, and response versus time profiles for a biophase model. $k_{el} = 0.4$, $k_{e0} = 0.5$, $E_{max} = 100$, $EC_{50} = 100$, $V = 1$, dose: 10, 100, 1000, and 10,000 units.

EFFECT OF k_{e0} ON SIGNATURE PROFILES. Figure 17.14 depicts the effects of changing k_{e0} on the signature profiles of a biophase model. The dotted line is the plasma concentration and the solid lines depict biophase concentrations at different values of k_{e0} . The value of the elimination rate constant, k_{el} is 0.4 and three profiles of biophase concentrations for k_{e0} values of 0.1, 0.4, and 1 have been plotted. When k_{e0} and k_{el}

Figure 17.14 Effect of different values of k_{e0} on shapes of hypothetical effect compartment. $k_{e0} = 0.1$, 0.4, and 1. $k_{el} = 0.4$. Dotted line, central compartment; solid lines, hypothetical effect compartment.

Figure 17.15 Schematic diagram of a mammillary two-compartment model.

are equal ($k_{e0} = k_{el} = 0.4$), the biophase and plasma profiles are not exactly parallel and the biophase profile seems curvilinear. In this case the explicit solution for the biophase compartment is slightly different and is outside the scope of this chapter. The terminal phase of the biophase concentrations is parallel to the plasma concentrations when value of k_{e0} is 1. When k_{e0} is 0.1, the terminal phase of the plasma concentrations and biophase concentrations are not parallel. Thus, this model has a flexibility of capturing PK-PD data where drug leaves the body but the effect still prevails, with values of k_{e0} less than the terminal phase of the PK profile.

DIFFERENCE WITH A MAMMILLARY TWO-COMPARTMENT MODEL. Figure 17.15 depicts a mammillary two-compartment PK model. C_P represents drug concentrations in the central (plasma) compartment and C_T represents drug concentrations in some hypothetical tissue compartment where the drug can distribute to. The first-order rate constant k_{el} represents the elimination rate constant for drug from the central compartment, and k_{12} and k_{21} are first-order rate constants representing distribution from plasma to tissue and tissue to plasma, respectively. Drug is eliminated only from the central compartment. Primarily, there are three disadvantages of using a two-compartment model instead of a biophase model. First, the number of parameters is one more than a biophase model since one has to use k_{12} and k_{21} instead of just k_{e0} . Second, if the plasma kinetics of the drug in monophasic, adding a tissue compartment will always make the plasma concentrations biphasic. In other words, a tissue compartment affects the concentrations of the plasma compartment. But the assumption of a biophase model is that the effect compartment does not alter the plasma concentrations. Third, no matter what value we use for k_{12} and k_{21} , the tissue concentrations will always decline parallel to the plasma concentrations for a two-compartment mammillary model. Whereas for a biophase model, the effect site concentrations do not decline parallel to the plasma concentrations for k_{e0} values less than the elimination rate constant.

INITIAL ESTIMATES. Figure 17.16 describes the method for estimation of k_{e0} . The rationale for taking the difference between time of peak effect and time of peak plasma concentration arises from the belief that the delay observed in effect is due to distribution of the drug to the effect compartment or biophase. If one had biophase concentrations, the time of peak biophase concentrations would be the same as the time of peak effect. Thus, the difference between peak times for effect and plasma concentrations provides the time required for distribution to biophase to be complete. Distribution is a first-order process governed by first-order rate constant k_{e0} . Thus, it

Figure 17.16 Determination of initial estimate of k_{e0} .

would take approximately four $t_{1/2, k_{e0}}$ for the distribution to complete. Hence, k_{e0} is calculated from Equations 17.22 and 17.23. An estimate of $E_{\max}$ can be obtained from the maximal response. EC_{50} estimate can be obtained from concentration at $\frac{1}{2} E_{\max}$ on down-curve of hysteresis arm:

$$t_{1/2, k_{e0}} = \frac{(t_{\text{peak, effect}} - t_{\text{peak, plasma}})}{4} \quad (17.22)$$

$$k_{e0} = \frac{0.693}{t_{1/2, k_{e0}}} \quad (17.23)$$

17.7.1.2.2 Indirect Response Models. “Indirect response” refers to a PD response that is produced when the drug acts on the production or dissipation of the endogenous factors that affect/control the response [53].

The basic equation for the scheme is provided below:

$$\frac{dR}{dt} = k_{\text{in}} - k_{\text{out}} \cdot R \quad (17.24)$$

where k_{in} is the zero-order production rate of response, R , and k_{out} is the first-order rate constant for the loss of response. Usually, R is measured as graded or continuous variable (Section 17.5). R begins at a baseline value and changes with time when a drug is administered and reaches back to its baseline value after the drug is out of the system.

When no drug is present, R has the baseline value R_0 , which is obtained by putting $dR/dt = 0$. Thus, $R_0 = k_{\text{in}}/k_{\text{out}}$.

For the basic indirect response models, four possibilities have been described (Fig. 17.17) [54]. The drug either inhibits or stimulates production or loss of response.

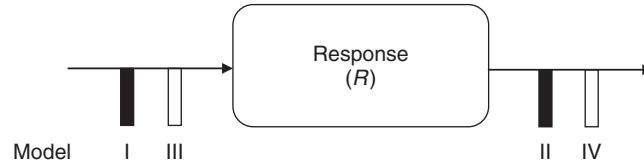

Figure 17.17 Schematic diagram for four basic indirect response models. Black solid bar indicates inhibitory function and white bar indicates stimulatory function.

The effect of the drug on the system can be asserted with the aid of a stimulatory or an inhibitory response. An inhibitory or a stimulatory response can be depicted as $I(t)$ and $S(t)$:

$$I(t) = 1 - \frac{I_{\max} \cdot C}{IC_{50} + C} \quad (17.25)$$

$$S(t) = 1 + \frac{S_{\max} \cdot C}{SC_{50} + C} \quad (17.26)$$

In these equations, C represents the plasma/blood concentrations of the drug. IC_{50}/SC_{50} is the concentration of the drug at half the maximal inhibitory/stimulatory effect. $E_{\max}$ or $S_{\max}$ represents the maximum effect of the drug on the response.

In the inhibitory equation, $I(t)$ assumes that $0 < I_{\max} \leq 1$. If the drug concentration is high enough to produce maximum inhibition of either production or loss of response, $I_{\max}$ is assigned a value of 1. The equation, then, is written in the following form:

$$I(t) = 1 - \frac{C}{IC_{50} + C} \quad (17.27)$$

MODEL I: INHIBITION OF PRODUCTION OF RESPONSE. The turnover equation for this model is as follows:

$$\frac{dR}{dt} = k_{in} \cdot \left[1 - \frac{I_{\max} \cdot C}{IC_{50} + C} \right] - k_{out} \cdot R \quad (17.28)$$

The inhibition of production causes the response to decrease with time to a minimum value and then a gradual return to the predose baseline. Model I has been applied to a variety of drug responses in the literature. Some examples would be reduction of pain [55] and temperature [56] by anti-inflammatory drugs, effect of corticosteroids on cortisol [57], and effect of histamine H_2 -receptor antagonists on the secretion of acid [58].

MODEL II: INHIBITION OF LOSS OF RESPONSE. The turnover equation for this model is as follows:

$$\frac{dR}{dt} = k_{in} - k_{out} \cdot \left[1 - \frac{I_{\max} \cdot C}{IC_{50} + C} \right] \cdot R \quad (17.29)$$

For model II, the signature profile looks opposite of model I. Since the loss of response is inhibited as the response increases with time and returns back to baseline.

Model II has been reported in the literature for cholinesterase inhibition as well as inhibition of water reuptake by diuretics [59]. Inhibition of water reuptake leads to increased diuresis.

MODEL III: STIMULATION OF PRODUCTION OF RESPONSE. The turnover equation for model III is as follows:

$$\frac{dR}{dt} = k_{in} \cdot \left[1 + \frac{S_{max} \cdot C}{SC_{50} + C} \right] - k_{out} \cdot R \quad (17.30)$$

For model III, the drug stimulates the production of the response. Thus, the response increases from baseline with time and then returns back to the baseline. The signature profile is similar to that of model II. In the literature, model III has been applied to bronchodilatory effects of terbutaline [50], growth-hormone-releasing effect of ipamorelin [60], as well as induction of prolactin secretion by a dopamine receptor antagonist [61].

MODEL IV: STIMULATION OF LOSS OF RESPONSE. In model IV, the drug causes stimulation of the loss of response. Thus, the signature profile is similar to that of model I. The response decreases after drug administration and then trends back to the baseline levels as the drug is eliminated from the system.

The turnover equation of this system is as follows:

$$\frac{dR}{dt} = k_{in} - k_{out} \cdot \left[1 + \frac{S_{max} \cdot C}{SC_{50} + C} \right] \cdot R \quad (17.31)$$

Model IV has been applied to terbutaline's effect on lowering plasma potassium levels [59,62]. As the plasma concentrations for terbutaline increase, the plasma potassium concentrations decrease, the peak of decrease in potassium concentrations is delayed by approximately half an hour.

DIFFERENCE BETWEEN BIOPHASE/LINK MODEL AND INDIRECT RESPONSE MODELS. The movement of drug in and out of the hypothetical distribution compartment might apparently look similar to the processes k_{in} and k_{out} . For a data set that should be fitted with an indirect response model if fitted with a biophase/link model would perform equally well for a single dose. The fits, however, would become worse with simultaneous fitting of more than one dose levels to obtain a common set of parameters. One of the primary reasons lies in the basic expectations from the two models. For biophase/link models, the maximum effect is expected to occur at the same time, whereas for the indirect response models, the peak effect is further delayed with increasing doses [54]. Data simulated with indirect response models when fitted with a biophase model produces different values of parameters with data for different dose levels [63–65].

SIGNATURE PROFILES. Figure 17.18 shows signature profiles for the indirect response models. A pattern of decrease and return to baseline is observed with models I and IV. An opposite pattern, increase in response and return back to baseline, is observed with models II and III. With an increase in dose, all the parameters, maximum response, initial slope, and $T_{max, effect}$ also increase. The peak response is delayed with increase in dose [66,67].

Figure 17.18 Signature profiles for four basic indirect response models. $V = 90$, $k_{cl} = 0.3$, $I_{\max} = 1$, $S_{\max} = 1$, $SC_{50} = 100$, $IC_{50} = 100$, $k_{in} = 9$, $k_{out} = 0.3$, $R_0 = 30$. Doses: 10–1000 units. (a) Model I, (b) model II, (c) model III, and (d) model IV. *Source*: Parameters obtained from Ref. 67.

TABLE 17.3 Initial Parameter Estimates for Basic Indirect Response Models

Parameter	Model I	Model II	Model III	Model IV
$I_{\max}/S_{\max}$	$\frac{(R_0 - R_{\max})}{R_0}$	$\frac{(R_{\max} - R_0)}{R_0}$	$\frac{(R_{\max} - R_0)}{R_0}$	$\frac{(R_0 - R_{\max})}{R_0}$
k_{in}	$-\frac{S_I}{I_{\max}}$	$\frac{S_I}{I_{\max}}$	$\frac{S_I}{S_{\max}}$	$-\frac{S_I}{S_{\max}}$
k_{out}	$\frac{k_{in}}{R_0}$	$\frac{k_{in}}{R_0}$	$\frac{k_{in}}{R_0}$	$\frac{k_{in}}{R_0}$
IC_{50}/SC_{50}	See Ref. 58 for the initial estimates for IC_{50}/SC_{50}			

INITIAL PARAMETER ESTIMATES. The details of initial parameter estimates have been provided by Sharma and Jusko [66]. Table 17.3 contains the equations to calculate the initial estimates.

17.7.1.2.3 Cell Life Span Models. This type of model has mainly found its application in the effect of substances, which stimulate the growth of cells in the body like the hematopoietic cells (RBC, etc.). Cell life span is defined as the time a cell spends in a population. Cell life span models assume that the loss of response (population of cells)

Figure 17.19 Basic one-pool cell model.

does not follow first-order processes but occurs due to natural senescence. A population of cells, R is controlled by two processes, a production rate and a loss rate [68]. Production can be due to physiological processes such as cell division, differentiation, and maturation, whereas cell loss may be due to senescence and random conversion to another type, such as hematopoietic cells. The following is the basic equation for the turnover of a cell population:

$$\frac{dR}{dt} = \text{production}(t) - \text{loss}(t) \quad (17.32)$$

Figure 17.19 shows a basic one-pool cell model. As mentioned previously, the loss process is assumed to be dependent on either natural senescence or conversion to another type of cells. Each cell lives for a specific period of time (T_R) and then dies or becomes another cell. The number of cells disappearing in a given time interval is equal to the number of cells generated. Or, the production rate is equal to that of the loss rate but delayed by T_R :

$$\text{Loss rate} = \text{production rate } (t - T_R)$$

The drug stimulates the production of response, which here is the cell population with a stimulatory function $S(t)$:

$$S(t) = \frac{S_{\max} \cdot C^\gamma}{SC_{50}^\gamma + C^\gamma} \quad (17.33)$$

where C is the concentration of the drug in the cell compartment, $S_{\max}$ is the maximum extent to which the production of cells can be achieved, and SC_{50} corresponds to the concentration at which the drug exhibits 50% stimulation of cell population. A Hill coefficient, γ , may be required to adjust for the shape of the response or can be set equal to one.

In this system, the production rate is described by the following equation:

$$\text{Production}(t) = k_{\text{in}} \cdot S(t) \quad (17.34)$$

Since loss rate is delayed by the life span of the cell (T_R), the equation for loss rate would be as follows:

$$\text{Loss}(t) = k_{\text{in}} \cdot S(t - T_R) \quad (17.35)$$

Thus, the basic one-pool cell model can be described by Equation 17.36:

$$\frac{dR}{dt} = \frac{k_{in} \cdot S_{max} \cdot C(t)^\gamma}{SC_{50}^\gamma + C(t)^\gamma} - \frac{k_{in} \cdot S_{max} \cdot C(t - T_R)^\gamma}{SC_{50}^\gamma + C(t - T_R)^\gamma} \quad (17.36)$$

$k_{in} \cdot S_{max}$ may be written as S_m and represents the maximum rate of cell production by the drug.

BASELINE (R_0). In the one-pool cell model depicted above, the production rate is equal to the loss rate and only delayed by the life span of the cell. The cells are produced by a zero-order rate constant k_{in} , which indicates that the number of cells born does not depend on the pool, R . In this scenario, the baseline value would be the same and not depend on any system parameters.

Thus, the value for the baseline was derived by Krzyzanski *et al.* [68] by assuming the production of cells was shut down. The equation thus obtained for the baseline is then expressed as follows:

$$R_0 = k_{in} \cdot T_R \quad (17.37)$$

PRESENCE OF AN ENDOGENOUS ACTIVE SUBSTANCE. If an endogenous compound stimulates the cell population, the baseline equation does not remain the same. Assuming a concentration of the endogenous compound to be C_0 , the baseline equation will now be basally stimulated as follows:

$$R_0 = k_{in} \cdot T_R \cdot \left(1 + \frac{S_{max} C_0^\gamma}{EC_{50}^\gamma + C_0^\gamma} \right) \quad (17.38)$$

SIGNATURE PROFILES. Figure 17.20a depicts the PK profiles of an agent which stimulates the production of cell population. PK was assumed to be one compartment with first order elimination with IV bolus dosing. Figure 17.20b depicts signature profiles for one-pool cell life span model for three dose levels. The rising part of the curves is entirely dependent on the production rate in an apparent zero-order manner. The profile reaches the peak exactly at the life span of the population [68]. After reaching its peak, the loss rate takes over and the response reaches the baseline. Figure 17.20c depicts the profiles at different values of T_R . As the values of T_R increase, the peak appears later as expected since the model predicts the peak to appear at T_R .

INITIAL ESTIMATES.

$$\begin{aligned} T_R &= T_{max} \\ k_{in} &= \frac{R_0}{T_R} \\ S_{max} &= \frac{R_{max}}{R_0} - 1 \\ S_I &= k_{in} \cdot S_{max} \end{aligned}$$

The estimate of S_{max} is reliable only at large doses since at smaller doses, true maximum effect is not achieved. S_I is the maximal initial slope.

Figure 17.20 Signature profiles for one-pool cell life span model. $k_{el} = 0.1$; $V = 1$; dose = 1, 10, and 100; $T_R = 24$; $S_{max} = 4$; $SC_{50} = 10$; and $\gamma = 1$. *Source*: Parameters obtained from Ref. 69.

APPLICATION OF CELL LIFE SPAN MODELS. Cell life span models have been applied mainly to drugs that alter the production of hematopoietic cells [69–76]. Woo *et al.* [74] studied the effects of recombinant human erythropoietin (rHuEPO) on reticulocytes, RBC, hemoglobin, and mean corpuscular hemoglobin (MCH) in rats. The four-pool cell life span model appropriately described the change in the PD parameters and generated life span values for two precursor compartments as well as for reticulocytes. To date, cell life span concepts have been only applied in case of rHuEPO and in one case for thrombopoietin (TPO) and recombinant human granulocyte colony stimulating factor (rHuG-CSF) [68].

17.7.1.2.4 Time-Dependent Transduction Models. Time-dependent transduction models have been used to describe the underlying mechanism for a delayed PD response as signal transduction or some unknown mechanism. Signal transduction is the process by which a cell converts an extracellular signal into a response. A typical signal-transduction process is shown in Fig. 17.21. The signal “s” enters the cell and binds to the receptor R. This signal–receptor complex can cause an immediate direct effect. On the other hand, the signal–receptor complex can also enter the nucleus and bind to the gene response element to cause a gene-mediated delayed effect. If the intermediate steps are not measured, the data could be modeled empirically with a transduction model. Ligands for nuclear hormone receptors, described in Section 17.2, cause signal-transduction cascade and can produce long delays in response. GPCRs and ion channels, on the other hand, do not produce this kind of long delays once a ligand binds to them. Figure 17.22 depicts typical PK-PD expectation for a time-dependent transduction model [77].

Figure 17.21 Schematic diagram for a signal-transduction process. *Source:* Adapted from Ref. 77.

The dotted line shows the PK profile and the solid line shows the PD profile. It is curious to note that the drug may be almost out of the system, but the PD marker is still at its baseline. In the case of biophase, indirect response (IDR), and cell life span models, the peak of the PD response appears later than the PK peak. However, in the case of transduction, one can see a significant delay, as depicted in (Fig. 17.22). Mathematically, the transit compartment technique is primarily used to model this delay between the PK and the PD response [78,79]. Figure 17.23 depicts a typical transit compartment model. $T_1, T_2, \dots, T_N$ are the transit compartments. Mathematically, the transit compartment model contains a series of differential equations (Eqs. 17.39–17.42), which describe a cascade of events between target occupancy and the PD effect. τ is defined as the mean transit time of signal from one compartment to the other and is assumed to be the same for all the compartments. γ is the power coefficient, which amplifies or dampens the signal of the transducer and is analogous to the Hill coefficient.

INITIAL ESTIMATES. The number of transit compartments (N), mean transit time (τ), and the power coefficient (γ) should be determined by fitting the model to the data:

$$\frac{dR}{dt} = \frac{1}{\tau} \cdot \left(1 - \frac{I_{\max} \cdot C}{IC_{50} + C} - R \right) \quad (17.39)$$

$$\frac{dT_1}{dt} = \frac{1}{\tau} \cdot (R - T_1) \quad (17.40)$$

$$\frac{dT_2}{dt} = \frac{1}{\tau} \cdot (T_1^\gamma - T_2) \quad (17.41)$$

$$\frac{dT_n}{dt} = \frac{1}{\tau} \cdot (T_{n-1} - T_n) \quad (17.42)$$

Figure 17.22 PK-PD expectation for a time-dependent transduction process. Dotted line, pharmacokinetics; solid line, pharmacodynamic expectation.

Figure 17.23 Transit compartment model for describing time-dependent transduction system.

SIGNATURE PROFILES. Figure 17.24 depicts the signature profiles for a single-step transduction process at different dose levels. The initial slope of these profiles is dose-independent. The time to peak effect is dose-dependent unlike biophase/link model. For medium to high dose levels, decline in response is parallel and inflection point represents the EC_{50} . The profiles mimic IDR model III (stimulation of k_{in}) for single-step processes but would not in case where multiple transduction processes exist. Figure 17.25a depicts the effect of increase in τ on the signature profiles for a transduction system. As τ increases, the profiles shift to later times and the maximum effect is diminished. Similarly, Fig. 17.25b depicts the effect of increase in the number of transduction compartments. The effect is similar to that of increase in τ . With an increase in the number of compartments, the profiles shift to later times and the maximum effect diminishes.

APPLICATIONS. Application of transduction models have been found in the literature in multiple therapeutic areas. These models have been applied to the cardiovascular area by Perlstein *et al.* [80]. A signal-transduction model with three delay compartments and a shape factor on the second compartment was used to capture the delay of the PD

Figure 17.24 Signature profiles for single-step transduction process. $V = 0.1$; $k_{el} = 1$; $E_{max} = 100$; $EC_{50} = 100$; $\tau = 1$.

Figure 17.25 The effect of τ and N on the signature profiles for a transduction system. (a) Effect of increase in the values of τ and (b) effect of increase in the number of delay compartments (N).

response. Delays in tumor growth have also been described extensively in the oncology area [81–85]. Lobo and Balthasar [81] modeled the delay in tumor growth using the killing rate constant with transit compartments. Simeoni *et al.* modeled the delay by dividing the tumor compartment into four transit compartments and called them *injured tumor cells*. The sum of all the injured cell compartments and the tumor compartment will produce the final response that is invariably a decrease in tumor weight [82].

17.7.2 Irreversible Effects

Effects such as cell killing and enzyme inactivation are known as *irreversible effects*. The response returns to the baseline not due to turnover of the response but due to growth of cells or synthesis of new enzymes. These agents generally covalently bind to the target, which promotes the destruction of cells/enzymes.

17.7.2.1 Cell Kill Models. This type of model was first applied by Jusko [86] in 1971. Figure 17.26 depicts the basic structure of the model.

R is the PD response, which is the number of cells in a population. The growth rate of the cells (describe by kilograms) is a first-order process and depends on the number of cells present in the population. The cells have their natural death governed by the first-order rate constant k . C represents the concentrations of the chemotherapeutic

Figure 17.26 Basic structure of a cell killing model.

Figure 17.27 Signature profiles for a cell killing model with nonlinear killing function. $V = 0.75$, $k_{el} = 0.3$, $k_g = 0.01$, $K_{max} = 0.1$, $KC_{50} = 10$. Dose = 0, 10, 100, 1000, and 10,000 units.

agent that stimulates cell death. The equation for this type of system is provided below:

$$\frac{dR}{dt} = k_g \cdot R - k \cdot C \cdot R \quad (17.43)$$

Integration of the above equation gives

$$R = R_0 \cdot e^{k_g t} \cdot e^{-k \cdot AUC_0^t} \quad (17.44)$$

Looking at the above equation, one might mistakenly think that killing of the cells is independent of time, but the time component is hidden in the AUC term.

Instead of a linear cell kill constant, a nonlinear cell kill constant can be used as well. The rate constant for killing, k , will be modified to the following equation:

$$k = \frac{K_{max} \cdot C}{KC_{50} + C} \quad (17.45)$$

Signature profiles for the cell killing model with a nonlinear kill rate function are depicted in (Fig. 17.27). Monoexponential decline of PK was assumed. The PD profiles show decline in response and the response returns beyond the baseline as one would expect since the response in proliferating cells grows when there is no drug in the system. The control curve, on the other hand, only grows since there is no drug in the system to kill the cells.

17.7.2.1.1 Initial Estimates. Figure 17.28 shows the method of determination of initial estimates from the model.

In Fig. 17.28, plotted on the Y-axis is the log of survival fraction (R/R_0) and plotted on the X-axis is time. The initial estimates for k_g and k are obtained from the following equations, where t_D is the doubling time of the cells and can be obtained from observed data:

$$k = -\frac{\ln S_F}{AUC_0^t} \quad (17.46)$$

$$k_g = \frac{0.693}{t_D} \quad (17.47)$$

Figure 17.28 Method for obtaining initial estimates for a basic cell kill model.

Figure 17.29 An irreversible enzyme inactivation model.

17.7.2.1.2 Applications. These models have been applied [87] to effect of piperacillin in studies of neutropenic mice infected with *Pseudomonas aeruginosa*. For all the doses, the survival fraction goes down, and as the drug is eliminated, the bacteria continues to grow again.

17.7.2.2 Model for Enzyme Inactivation. The structure of a typical enzyme inactivation model is depicted in Fig. 17.29.

R represents the enzyme concentrations. The enzyme is produced by a zero-order rate constant k_{in} and a first-order rate constant k_{out} . $f(C)$ represents the irreversible effect of the drug on the turnover of the enzyme. In absence of drug C , the model is similar to a turnover model, where $R_0 = k_{in}/k_{out}$. Equation 17.48 shows the turnover of the enzyme in presence of the drug. The effect of the drug can either be linear or represented by an E_{max} function. Equations 17.49 and 17.50 describe the two types of drug effect:

$$\frac{dR}{dt} = k_{in} - k_{out} \cdot R - f(C) \cdot R \quad (17.48)$$

$$f(C) = k \cdot C \quad (17.49)$$

Figure 17.30 Signature profiles for an irreversible enzyme inactivation model. $k_{el} = 0.3$, $V = 1$, $k_{in} = 10$, $k_{out} = 0.1$, $k = 0.01$. Dose = 10, 100, and 1000 units.

$$f(C) = \frac{K_{max} \cdot C}{KC_{50} + C} \quad (17.50)$$

17.7.2.2.1 Signature Profiles. Figure 17.30 depicts the signature profiles for enzyme inactivation model at a range of doses. The response declines from baseline to a minimum and returns back to the baseline with time. There is a dose-dependent shift in the maximal effect; however, the peak effect occurs earlier unlike indirect response models, where peak effect occurs later at higher doses [88].

17.7.2.2.2 Applications. The basic turnover-irreversible model has been applied to inhibition of gastric acid secretion of pantoprazole [89]. This model was further used to simulate reduction in acid secretion at 40-mg dose to validate the model. The model was further validated by integration of clinical data, which showed reduction in time to maximal effects with an increase in concentrations or dose as well as higher infusion rates. This kind of model has also been applied to antiplatelet effects of aspirin [90].

17.7.3 Other Models

17.7.3.1 Disease Progression Models. Clinical pharmacology is a combination of how a disease progresses and the effect of drug on the progression of disease. It was first indicated by Holford and Sheiner in 1981 that the baseline in patients, which we use in an E_{max} model (E_0), is not a constant number. The change in E_0 over time should be taken into consideration while analyzing the clinical data [91]. The progression of disease refers to time course or trajectory of a biomarker or a PD or clinical end point, which is a measure of the clinical status of the patient. This trajectory of the disease progression can be linear, nonlinear, or cyclical. Thus, a model for progression of a disease should incorporate these factors with mathematical function to describe the time course of disease progression [92]. Also, there may be situations where the disease conditions change the underlying PK and PD. These changes should also be incorporated during analysis of clinical data and clinical trial simulations.

17.7.3.1.1 Effects of Drugs in Disease Progression. The effect of a drug on the disease progression may be of three types [93]. Figure 17.31 depicts the three types of drug effects on disease progression.

Figure 17.31 Types of effects of different drugs on disease progression.

SYMPTOMATIC. The effect of a drug is named symptomatic if it has a beneficial effect on the disease but does not change the underlying process of the disease or the trajectory of the disease. The drug delays the progression of the disease, and as the drug exits the system, the disease follows its normal path. This type of drug effect has been seen with tacrine in the treatment of Alzheimer's disease [94]. The drug delays the deterioration of the patient by six months, and as soon as the therapy is stopped, the deterioration follows its natural path.

DISEASE MODIFYING OR PROTECTIVE. A drug is said to be protective or disease modifying if it interferes with the natural history or trajectory of the disease and causes a permanent change. Thus, the effect remains even after the drug has been eliminated or therapy has been stopped. Protective effects may be of two types, one which alters the time course of progression of the disease and the other which changes the maximal status of the disease.

CURATIVE. The effect of a drug is said to be curative if the therapy completely arrests the progression of the disease. Again, removal of drug from the system or stopping of therapy keeps the patient in the state before the disease started [92]. Chemotherapeutic agents such as antibacterial agents and some anticancer agents exhibit curative effects.

17.7.3.1.2 Models of Disease Progression.

LINEAR MODELS. The linear model of disease progression is the simplest model used to describe the time course of progression of several diseases. The model assumes that the patient has a baseline disease condition S_0 and a slope α , which is responsible for the change in the disease condition with time. Equation 17.51 shows the disease model without the effect of the drug:

$$S(t) = S_0 + \alpha \cdot t \quad (17.51)$$

A disease progression model is built in two steps. First, the model for the disease is built and then the effect of the drug is added to it. Equation 17.52 shows the effect of the drug $[f(C)]$:

$$S(t) = S_0 + \alpha \cdot t + f(C) \quad (17.52)$$

Equation 17.52 shows a symptomatic drug effect on the disease. The drug does not act on α . Once the therapy is stopped or the drug goes out of the system, the same slope α resumes. Equation 17.53, on the other hand, shows the protective effect of the drug. In this case, the drug acts on the slope α , and at the end of therapy, the value of α changes to a different value, α' :

$$S(t) = S_0 + (\alpha + f(C)) \cdot t \quad (17.53)$$

ASYMPTOTIC MODELS. The linear models have their own disadvantages. They are useful for time frames that are mainly linear. Also, the biological systems, more often than not, change nonlinearly with time. Thus, asymptotic models are often used to describe a variety of diseases. There are different kinds of asymptotic models used in the literature to describe different disease processes. These models are named so since they are associated with some kind of plateau of the disease biomarker. Table 17.4 depicts different types of disease models and the effect of drugs on the disease.

Apart from the examples shown in Table 17.4, other asymptotic models can be used such as inverse Bateman function [92] and cyclical modification of inverse Bateman function [92].

GROWTH MODELS. Apart from all the linear and asymptotic models, different types of growth models have also been used to describe disease progression. A Gompertz-type growth function has been used to describe the time course of Parkinson's disease [92], as depicted in the following equation:

$$\frac{dR}{dt} = \beta \cdot R \cdot (\beta_{\max} - R) - (k_{\text{death}} \cdot R) \quad (17.54)$$

In addition to these models, transit compartment models have also been used to describe a time course of disease [92].

TABLE 17.4 Asymptotic Models of Disease Progression and Effect of Drug on Disease

Model	Equation	Symptomatic Drug Effect	Disease Modifying or Protective Drug Effect	References
Exponential	$S(t) = S_0 \cdot e^{-k_{\text{PROG}} \cdot t}$	$S(t) = S_0 \cdot e^{-k_{\text{PROG}} \cdot t - f(C)}$	$S(t) = S_0 \cdot e^{-[k_{\text{PROG}} + f(C)]t}$	87
E _{max} function	$S(t) = S_0 + \frac{S_{\max} \cdot t}{SC_{50} + t}$	$S(t) = S_0 + \frac{S_{\max} \cdot t}{SC_{50} + t} \pm f(C)$	$S(t) = S_0 + \frac{S_{\max} \cdot [1 + f(C)] \cdot t}{SC_{50} \cdot [1 + f(C)] + t}$	88,89
Nonzero asymptotic function	$S(t) = S_0 \cdot e^{-k_{\text{PROG}} \cdot t} + S_{\text{ss}} \cdot (1 - e^{-k_{\text{PROG}} \cdot t})$	$S(t) = S_0 \cdot e^{-k_{\text{PROG}} \cdot t} + S_{\text{ss}} \cdot (1 - e^{-k_{\text{PROG}} \cdot t}) \pm f(C)$	$S(t) = S_0 \cdot e^{-k_{\text{PROG}} \cdot [1 + f(C)] \cdot t} + S_{\text{ss}} \cdot (1 - e^{-k_{\text{PROG}} \cdot [1 + f(C)] \cdot t})$	84

Figure 17.32 Schematic diagram of a precursor-dependent indirect response model.

17.7.3.2 Models of Tolerance and Rebound. As defined in Section 17.2, tolerance is referred to as a *phenomenon where the response to the drug exposure is diminished due to repeated administration of the drug*. This phenomenon might be observed in the clinic as well as in preclinical species and has been described by the following PD models.

17.7.3.2.1 Precursor-Dependent Indirect Response Model. This model describes the phenomenon of tolerance and rebound in case of indirect PD responses. The model in general shows how a drug can affect a precursor pool by stimulation or inhibition of the elimination of the precursor. The structure of the model is depicted in (Fig. 17.32). Precursor P is synthesized by a zero-order rate k_0 and lost by the first-order rate k_s . Precursor is converted to response R by a first-order rate k_p . The response, R , is dissipated by a first-order rate k_{out} [95]. The drug either stimulates or inhibits the conversion of the precursor to the response by inhibitory $I(t)$ or stimulatory $S(t)$ functions as follows. The rate of change of response and the precursor can be described by the following set of differential equations:

$$\frac{dP}{dt} = k^\circ - k_p(1 \pm H(t)) \cdot P - k_s \cdot P \quad (17.55)$$

$$\frac{dR}{dt} = k_p(1 \pm H(t)) \cdot P - k_{out} \cdot R \quad (17.56)$$

$H(t)$ represents either stimulatory or inhibitory Hill functions, as described by the following equations:

$$S(t) = 1 + \frac{S_{max} \cdot C}{SC_{50} + C} \quad (17.57)$$

$$I(t) = 1 - \frac{I_{max} \cdot C}{IC_{50} + C} \quad (17.58)$$

The signature profiles for the stimulation model after four doses starting from 10 units to 10,000 units are shown in Fig. 17.33. In precursor-dependent IDRs, rebound is mainly due to depletion (stimulation model) or accumulation (inhibition model) in the amount of precursor with time, flowing into the drug compartment. The maximal effect increases with increase in dose. The effect reaches the baseline and further goes down producing rebound. The peak of the rebound shifts toward later time points with dose. Figure 17.34 depicts the effect of multiple dosing on the signature profiles of a

Figure 17.33 Signature profiles from a precursor-dependent indirect response model. $k_{el} = 0.3$, $V = 1$, $R_0 = 15$, $P_0 = 300$, $k_p = 0.1$, $k_s = 0$, $k_{out} = 2$, $E_{max} = 1$, $EC_{50} = 100$.

Figure 17.34 Development of tolerance during multiple dosing for a precursor-dependent IDR. Dose of 100 units given at an interval of 12 h. Dotted line, multiple dose pharmacokinetics; solid lines, multiple dose pharmacodynamics for models with and without precursor.

precursor-dependent indirect response model. Plotted in the same graph is the mono-exponential PK profiles and two PD profiles, one with the precursor compartment and the other without precursor compartment. The profile without the precursor compartment increases with multiple dose and reaches steady state as the PK reaches steady state with a slight delay in the peak times. When a precursor compartment is added, the PD response decreases with the first three doses and then achieves a steady state with response values much less than that achieved by the model without a precursor compartment. Thus, the model with a precursor compartment exhibits tolerance with multiple doses.

17.7.3.2.2 Counterregulatory Model. This type of model relies on the opposing effect acting on the response. The formation of the modulator is dependent on the response and a first-order rate constant, k_1 , and dissipates with the rate constant k_2 .

The turnover of the modulator is provided by the following equation:

$$\frac{dM}{dt} = k_1 \cdot R - k_2 \cdot M \quad (17.59)$$

The modulator compartment is then introduced into the mechanistic PD model as an opposing effect. The following equation shows such a modulator effect on an indirect response model:

$$\frac{dR}{dt} = k_{in} - k_{out} \cdot \left[1 - \frac{I_{max} \cdot C}{IC_{50} + C} \right] \cdot R \cdot (1 + M) \quad (17.60)$$

Counterregulatory models in their various forms have been used a multiple times in the literature [96,97]. Bauer and Fung developed a counterregulatory model to account for the effect and generation of tolerance by nitroglycerine in a rat model [97]. Counterregulatory mechanisms have been introduced in the indirect response model of diuresis to account for tolerance development by furosemide [97].

17.8 TOOLS AND SOFTWARES COMMONLY USED IN PK-PD MODELING

PK-PD modeling requires a computer to undergo iterative procedure to generate PK and PD parameters. Various softwares have been used from the inception of this kind of data analysis. Various softwares used are WinNonlin, ADAPT II and V, Matlab (extensively used in chemical engineering as well), SAAM II, Phoenix, and SAS for individual analysis. For population modeling, more popular softwares are NONMEM, S-ADAPT, R, S-PLUS, SAS, WinNonmix, ADAPT V, and Phoenix. For simulations, Berkeley Madonna is extensively used. Simulations for this chapter were performed with WinNonlin [98], ADAPT V [99], and Berkeley Madonna [100]. GraphPad Prism [101] was used for plotting the simulated data.

17.9 CONCLUSIONS

In order to perform and apply PK-PD modeling successfully, one requires a sound understanding of various disciplines such as biology, pharmacology, and mathematical and statistical sciences. Knowledge of biology and pharmacology helps in understanding a disease and therefore choosing the right biomarker for the development of a disease model. Modeling has diverse applications in both drug discovery and development, starting from understanding of efficacy animal models through dose selection for FIH studies, and throughout drug development.

17.10 FUTURE PERSPECTIVES: SYSTEMS MODELING

A recent interest in the area of PK-PD modeling is the development and application of systems modeling in drug discovery and development. Systems modeling refer to modeling a system such as heart or lung using same mathematical principles as used

in classical PK-PD modeling. Modeling has been thriving on applied mathematics to understand the quantitative relationship between kinetics of drug in the body and its effect [102]. Systems model mainly refer to the development of physiologically based disease progression models to which a drug effect can be incorporated. Modeling efforts in physiology have resulted in organ models such as the human lung model [103] and the lumped heart model [104]. Building similar systems with progression of disease is the latest challenge in PK-PD modeling. Once such a model has been built, drug effect can easily be incorporated. Some initial efforts have been made in this area recently by Landersdorfer and Jusko [105] and Danhof and colleagues [106]; however, the area is still in its evolution stage. A recent white paper from NIH states that, “quantitative systems pharmacology will create understanding of disease mechanisms and therapeutic effects that span biochemistry and structural studies, cell and animal-based experiments and clinical studies in human patients” [107].

ACKNOWLEDGMENTS

The authors would like to thank Dr. William J. Jusko, PhD, since materials from his publications were extensively referred in the preparation of this chapter. The authors thank their colleagues within Bristol-Myers Squibb, US, Punit Marathe, PhD, Michael Sinz, PhD, and Joseph Raybon, PhD, and also thank Jasminder Sahi, PhD, for their valuable suggestions and comments.

18.1 INTRODUCTION

The drug discovery and development process involves several sequential steps, from target identification, computational modeling, medicinal chemistry, biological screening, lead generation and optimization, preclinical and clinical studies to final registration of a drug. The past two decades of drug discovery research and development witnessed an explosion of technological advances but with little success in increasing the approvals of new drugs reaching the market each year. The cutting-edge technologies developed in the past two decades include miniaturized high throughput screening assays, genetically modified animal models, ultra-sensitive liquid chromatography (LC)–mass spectrometry (MS)/MS systems enabled with structure

elucidation tools, advanced imaging systems, nano-technology, siRNA technology, OMICS (genomics, proteomics, and metabonomics), and many more. However, these technological advances have not been meaningfully translated for success of new drugs reaching the market. The number of new drugs approved now is no greater than 50 years ago, that is, between 20 and 30 drugs, although mid 1990s have seen approvals of up to 50 new chemical entities (NCEs). Alongside, the cost of new drug development has been escalating 13.4% annually since 1950s and recently has been estimated between US\$1.3 and 1.7 billion, although these estimates have been debated [1]. Therefore, in retrospect, these facts warrant a critical review of factors that impede the success of new drugs reaching the market.

A review of the reasons of failures of drug approval for human use in the past three decades indicates that the major reason from the 1960s through the 1980s was unfavorable pharmacokinetics (PKs; 39%) in phase 1 clinical trials [2], while failures due to lack of efficacy and safety were estimated to be 30% and 10%, respectively (Fig. 18.1a). Early assessment of PK liabilities in drug discovery using *in vitro* and *in vivo* approaches led to reduced number of failures (14%) in phase 1 clinical trials (Fig. 18.1b) [3]. Nevertheless, during late 1990s to early 2000, failures due to safety issues escalated to 43% with minimal change in efficacy failures (36%), which can be attributed to enhanced drug exposures due to improved PK profiles of the drug candidates. In 2010, several drugs failed in phase 3 trials (Table 18.1) due to lack of efficacy, although the results until phase 2 trials were promising. During 2007–2010 [4], almost 90% of failed phase 3 trials were either due to lack of efficacy (66%) or safety issues (21%; Fig. 18.1c). Among these failures, about 28% drugs were for oncology targets and 18% for neurological disorders (Table 18.2). This is a very important factor to consider as many pharmaceutical companies ignored the complexity of biology in rational drug design and discovery. As Arrowsmith stated, “propensity to assume that success in one disease will translate into success in new and significantly different disease. This is particularly apparent in oncology, for which success in one tumor type has been assumed to translate into success in variety of other tumors, without firm evidence that the mechanism of action remains relevant” [5]. For example, sunitinib (Sutent, Pfizer) was approved in 2006 for renal cell carcinoma and imatinib-resistant gastrointestinal (GI) stromal cell carcinoma and subsequently for rare pancreatic neuroendocrine cancers [6]. However, between April 2009 and May 2011, Pfizer has reported unsuccessful late-stage trials with sunitinib in breast cancer, metastatic colorectal cancer, advanced nonsmall-cell lung cancer, and castration-resistant prostate cancer. These failures clearly indicate that mechanisms of tumor development are different from one organ to another. Forcing drug candidates into expensive late-stage clinical trials for additional multiple indications than the one initially sought after can contribute to poor success of drug approval, due to lack of mechanistic mode of action of the drug candidate. Another point to consider is that predictive value of proof-of-concept (POC) trials in animal models is inadequate and in certain cases may not translate to desired clinical outcome [7]. Frye *et al.* [8] points out that about 49% of known targets have not been validated for efficacy in humans, thus widening the gap for discovering novel drugs for unmet medical needs. With the availability of complete human genome sequence data, along with understanding their functions, the number of potential drug targets are expected to increase from the 500 or so that underlie our current pharmacopeia to potentially tens of thousands [9]. Thus, in the future, more preclinically and clinically unvalidated targets will be added to new drug discovery research.

Figure 18.1 Pie-charts representing (a) pharmacokinetics contributing to (39%) drug failures, while failures due to lack of efficacy and safety were estimated to be 30% and 10%, respectively, (b) PK liabilities in drug discovery using *in vitro* and *in vivo* approaches led to reduced number of failures (14%) in phase 1 clinical trials, and (c) almost 90% of failed phase 3 trials were either due to lack of efficacy (66%) or safety issues (21%). (See color insert.)

Translational research offers promise to close the gaps between efficacy and safety outcomes from animal disease models and those in patients through rational drug design [9]. Rational drug discovery requires an early assessment of all factors affecting the likely success of a drug candidate in the subsequent preclinical and clinical phases of drug development. These factors include pharmacology, physico-chemical properties, drug permeability, transport, absorption, drug metabolism (DM), and toxicology.

TABLE 18.1 Top 10 Phase III Failures During 2010

Drug Name	Chemical Class	Company	New Indication	Unmet Need?	Reason for Failure
Dimebon (latrepirdine)	Small molecule	Pfizer/Medivation	Alzheimer's, Huntington	Yes	No efficacy
Ocrelizumab	Monoclonal antibody	Roche	Rheumatoid arthritis	Yes	No efficacy
Taspoglutide	GLP1 analog ^a	Roche	Type 1 diabetes	Yes	Serious side effects
Semagacestat	Small molecule	Eli Lilly	Alzheimer's disease	Yes	No efficacy
ASA404 (vadimazen)	Small molecule	Novartis/Antisoma	Nonsmall cell lung cancer	Yes	No efficacy
NOV-002	Glutathione disulfide mimetic	Novelos	Oncology in combination with chemotherapy	—	No efficacy
Zibotentan	Small molecule	Astra Zeneca	Nonmetastatic prostate cancer	—	No efficacy
Vicriviroc	Small molecule	Schering/Merck	HIV-1	Novel target (CCR5)	No efficacy
Recentin (cediranib)	Small molecule	Astra Zeneca	Metastatic colorectal cancer	—	Poor efficacy compared with avastin
NV1FGF	pCOR ^b DNA plasmid	Sanofi aventis	Critical limb ischemia (PAD) ^c	—	No efficacy

^aGlucagon-like peptide 1 analog.^bpCOR, conditional origin replication.^cPeripheral arterial disease.

The use of mechanistic PK–PD models early in the drug discovery process along with novel biomarker monitoring could potentially reduce attritions during late-stage drug development. The advances in automation of analytical technologies has dramatically improved our ability to dissect out the fundamentals of absorption, distribution, metabolism, excretion, and toxicology (ADMET) liabilities through the development of powerful *in silico* and high throughput screening methods. This is fueling a shift away from the conventional nature of ADMET assessment toward a more rational, *in cerebro* approach to drug design. On the other hand, PD models have also considerably shifted from traditional approaches to molecular biology approaches in dissecting the cell signaling pathways, humanized animal models, and imaging tools to select appropriate and selective biomarkers that play causal role (not casual) in assessing drug efficacy and safety. These advances in technologies are being increasingly employed in mechanistic

TABLE 18.2 Phase III and Submission Failures According to Therapeutic Area During 2007–2010

Therapeutic Area (Total $n = 83$ Compounds)	Failures (%)
Anticancer (23)	28
Nervous system (15) ^a	18
Alimentary and/or metabolism (11) ^b	13
Anti-infectives (11)	13
Cardiovascular (7)	8
Other (16)	19

^aIncludes neurodegenerative diseases.^bIncludes diabetes and obesity.**Figure 18.2** Provides an overview of the key areas in the drug discovery and development and highlights the central role of pharmacokinetics and drug metabolism in the process. (See color insert.)

PK–PD studies during early drug discovery to select promising candidates for drug development.

This chapter provides an overview of the drug discovery process with special emphasis on integrating medicinal chemistry with pharmacology, DMPK, and toxicology (Fig. 18.2). Key PK–PD concepts combined with applications of recent advances in DM, drug transport (DT), exploratory toxicology, and biomarker tools allow accurate prediction of clinical efficacy and safety during preclinical evaluation. The strategic use of translational PK–PD approaches starting from early drug discovery through late-stage clinical development for a successful realization of drug product with minimal failures are discussed in the following sections.

18.2 DRUG DISCOVERY PROCESS

Current state of the art in drug discovery involves at least three phases (Fig. 18.3). During the *first* phase, computational modeling, which is also popularly known as *in silico modeling* or *virtual screening*, is used. Software have been developed in the past two decades (Table 18.3) using proprietary and nonproprietary databases that include physico-chemical, enzyme/receptor docking, and ADMET properties. These databases help a computational modeling scientist to design “drug-like” chemical structures for a particular biological target of interest.

During the *second* phase of drug discovery, computational scientists feed these data to medicinal chemists who then attempt to synthesize the “drug-like” molecules of interest. It is also imperative that patent liabilities be considered before synthesis is initiated. These molecules then are screened in various pharmacological assays to identify molecules with “drug-like” properties.

During the *third* phase of drug discovery process, which is known as *lead optimization stage*, the medicinal chemists handover the molecules to ADMET scientists who conduct various *in vitro* and *in vivo* ADMET evaluations to generate “leads” with drug-like properties with minimal ADMET liabilities. These leads are then advanced by the regulatory scientists who will initiate investigational new drug (IND), enabling studies for submission to regulatory authorities.

The three phases of drug discovery may be iterative as a cyclical process until there is consensus among computational scientist, medicinal chemist, pharmacologist, and ADMET scientist for the quality of leads generated. At an early phase, it is essential that the pharmacokineticist, pharmacologist, and toxicologist collaborate on building PK–PD and toxicokinetics (TKs)–toxicodynamics relationships that can predict efficacious clinical dose and appropriate desired clinical response with broad therapeutic index.

Figure 18.3 Gives an overview of the different stages of drug discovery process and highlights the contributions of virtual screening and computational biology in the lead identification and optimization process.

TABLE 18.3 *In Silico* Software Used in Drug Discovery

Software	Application	License
Accelrys Discovery Studio	Molecular modeling, docking	Commercial

18.2.1 Computational Modeling and Simulations in Drug Discovery

Computational analyses play a big role in drug target identification and validation and also in lead identification and optimization. A lead compound is one that is believed to have potential to treat disease without having serious life-threatening adverse effects.

Microarray analysis for example is often used to profile gene expression and pick genes that are differentially expressed and may be potential drug targets or biomarkers for the underlying pathology [10,11]. More extensive experimentation and time series analysis of the gene expression signatures is becoming routine due to the widespread availability and affordability of standardized microarrays. Proteomic technologies hold out a similar promise and protein microarrays are gaining wider acceptance [12]. However, these technologies generate a humongous amount of data that need to be effectively stored, cleaned, transformed, and finally analyzed using statistical and data-mining tools. Depending on the desired endpoint, this can result in discovery of new drug targets or validation of existing ones. It can also help in profiling toxicity-related gene signatures for a given molecule [13]. The initial data are in the

form of images that need to be analyzed using imaging software to estimate the signal strength of the genes. Later, this signal or expression data are analyzed using unsupervised clustering methods such as principal component analysis, expectation minimization, statistical methods (analysis of variance and analysis of covariance), and machine learning algorithms such as support vector machines. Visualization techniques are also frequently employed [14]. While there are several commercial software for genomic analysis, the predominant current platform is “R.” This is an open-source statistical language and analysis platform with extensive modules for data mining of genomics and proteomics [15]. Several companies, including Amazon (EC2) and revolution analytics (<http://www.revolutionanalytics.com>), offer “R” on the “cloud” to enable distributed scalable life science data analysis. Academic research centers such as the European Bioinformatics Institute also offer cloud-based “R” analysis for microarray data (<http://www.ebi.ac.uk/Tools/rccloud/>).

18.2.1.1 Pharmacophore Modeling Tools. Assuming that the protein drug target is known and its three-dimensional (3D) structure is available, molecular modeling tools such as PyMol (PyMOL Molecular Graphics System 2002) [16] and Chimera, are used to probe its structure and locate the binding sites [17]. In case of enzymes, these may be substrate or cofactor/coenzyme sites or other allosteric sites. Since the idea is to find small molecules that bind to these sites, open-source software such as AutoDock4 [18] and Autodock Vina [19,20] may be used to simulate the binding energies. Small molecule ligands with good docking scores and correct binding mode may indicate potential leads.

The ZINC database together with PubChem are good sources of small molecule ligand libraries. One can also construct custom combinatorial libraries using small molecule fragment/reagent databases from companies along with library generation tools. Available chemicals directory (Accelrys Inc.) (ACD) and comprehensive medicinal chemistry database (Accelrys Inc.) (CMC) are some of the fragment-like databases frequently used to this end.

It is important to note that results from such docking simulations using different tools, both commercial and open source, may differ widely, depending on the size and flexibility of the protein and the ligand. This approach is referred to as *virtual screening* or virtual high throughput screening (*vHTS*) and is the computational equivalent of high throughput screening. Most top bioinformatics vendors have well-established tools for docking and protein modeling. There are several open-source software that facilitate distributed vHTS [21].

Irrespective of whether the protein structure is available, if a ligand, say an inhibitor, cofactor, or substrate is known, it is often fruitful to use ligand-based similarity approaches for lead identification [22]. These include 2D similarity searching using fingerprints, functional groups, and atom-neighborhood descriptors. Many of these approaches are available as part of the Open Babel and Mayachemtools software. For scientists not familiar with command line tools, there are software such as Knime™ and Taverna, which enable development of workflows for fingerprint calculation, similarity searching, and many other tasks.

Leads may also be discovered by 3D similarity searching based on shape and molecular electrostatic potential as exemplified by OpenEye tools and open-source alternatives such as Shaep [23]. Some software, such as Inte:Ligand LigandScout, allow forming a negative image of the binding site as a pharmacophore for further shape searching.

Although the terms *chemoinformatics* and *computational chemistry* are sometimes used interchangeably, there are key differences between the two approaches. Computational chemistry-based approaches are generally based on 3D information, energy minimization, and forcefields and cheminformatics approaches focus on occurrence of particular patterns of chemical substructures based on graph theory. Both approaches are complementary and should be used in tandem for lead identification wherever applicable.

18.2.1.2 ADMET Modeling Tools. The chemical structure so obtained needs to satisfy several criteria befitting a “good” lead. Lipinski’s “rule of five” is in widespread use for filtering chemical libraries for good absorption, distribution, metabolism, and elimination (ADME) properties. Recent attempts have led to the “Pan Assay Interference Compounds (PAINS)” filter, useful to identify and remove promiscuous, reactive, unstable, and potentially toxic molecules [24]. Absorption and metabolism properties may be modeled using Gastroplus or Simcyp software. Toxicity prediction algorithms may also be used at this stage to rank the compounds. Most of the toxicity predictions can be conducted using commercial software such as TopKat and DEREK™. Computational toxicity prediction includes quantitative structure property relationship (QSPR) models, for example, TopKat, case-based reasoning (MultiCASE), and rule-based expert systems (DEREK).

Once a few leads are obtained, and if the patent and synthetic landscape is clear, attention shifts to changing the lead(s) so as to preserve activity but optimize ADMET properties. Products from companies such as ACDlabs allow one to filter fragments/substructures based on properties and replace certain parts of the lead so as to optimize them. Although it allows one to explore a large chemical space, multifactorial optimization is inherently difficult and not always achievable computationally where considerable input is necessary from medicinal chemists and ADMET scientists. As an example, aqueous solubility of the lead can be computationally modulated to attain better intrinsic solubility or $\log S$. Similarly, other substructure modifications may reduce the $\log P$ or increase the microsomal stability [25].

Leads can also be optimized computationally for cytochrome P450 (CYP) inhibition [assessing for potential drug–drug interactions (DDIs)], human ether-a-go-go-related gene (hERG) inhibition (assessing for potential cardiac arrhythmias), and other ADMET properties. It is important to note that computational optimization has to be constrained by experimental data wherever available. Most models for physicochemical properties such as $\log S$, $\log P$, $\log D$, and pK_a are based on a limited training set and the predictions may not be very useful for molecules with diverse chemistry.

Knime is a useful bioinformatics and cheminformatics “aware” workflow development software, which has plugins for descriptor, fingerprint, calculation, substructure searches, integration of high content screening data, “R” analytics plugins for microarray data, and more [26]. Bioclipse is an open-source cheminformatics software, based on the Eclipse™ Integrated Development Environment platform. It has plugins for QSAR, Phase I metabolic hotspot prediction and Carcinogenicity and Mutagenicity alerts. Several other plugins for toxicity prediction are available in the OpenTox version of Bioclipse. The OpenTox Bioclipse version also includes Caco-2 models. Toxtree is another useful software for toxicity predictions. Of late, regulatory agencies such as US food and drug administration (FDA) and organisation for economic co-operation and development (OECD) have taken considerable interest in computational methodologies and their toolbox has an impressive array of models and cheminformatic capabilities.

Table 18.3 lists the applicable license and the task for which they can be applied. Starting with drug target identification and validation, computational approaches facilitate the discovery of novel biologically active small molecules with a good ADMET profile (lead identification), which can then be optimized (lead optimization). These methodologies raise flags that may identify significant issues with the molecules and simultaneously expand the chemical space that can be explored by orders of magnitude. The virtual and potentially virtuous methods can help prioritize drug discovery efforts by guiding, but not replacing, human intuition.

18.2.2 Lead Identification, Optimization, and Selection Process in Drug Discovery

The objective of this step is to ensure the lead has optimal pharmaceutical properties assuming these properties will lead to successful clinical outcome to market the NCE as a drug. This process involves a multidisciplinary approach involving a medicinal chemist, biologist/pharmacologist, ADMET scientist, and clinician with sound understanding about the target patient population and at times involves contributions from marketing, formulation, and regulatory representatives. This team meets frequently to understand and discuss the action plans for the gaps in science, regulatory, and commercial challenges that may be encountered and clinical value the drug candidate offers to the patient.

This process is crucial for nominating a compound with ideal pharmaceutical properties for successful preclinical and clinical development. It is therefore critical to optimize pharmaceutical properties of the drug candidate at an early stage of drug discovery with limited data. Table 18.4 lists ideal pharmaceutical properties to help determine whether a candidate compound has potential to be developed as a drug. Failure to comply with these properties may have adverse consequences, including ADMET liabilities and lack of efficacy in advance stages of drug development.

18.2.2.1 Pharmacokinetics or Absorption, Distribution, Metabolism, and Excretion.

PKs (pharmaco-drug and kinetic-movement) is the quantitative study of the time course of drug ADME processes. PK is the science that describes the movement of drugs in the body [27]. A basic tenet of PK is that the magnitude of both the desired therapeutic response and/or toxicity of a drug are a function of its concentration in the body [27,28]. Successful pharmacotherapy is often dependent on maintaining the drug concentrations within a defined range, which is efficacious while being safe or has a favorable therapeutic index. PKs is one of the primary considerations, in the selection of a drug candidate, during early drug discovery phase. This is discussed extensively in the chapters titled *Pharmacokinetics and Toxicokinetics in Drug Discovery and Development* and *Pharmacokinetic Data Analysis and Modeling of ADME Processes* of this volume. Many virtual pharmaceutical companies, due to limited funding, skip *in vitro* permeability assays and directly proceed for *in vivo* PK studies in mice or rat. The argument is that if a compound is sufficiently bioavailable, it must pass through biomembranes. These *in vivo* PK methods can be applied only for a limited number of compounds and may not be useful for screening numerous compounds. Some companies conduct cassette dosing where 5–6 compounds are simultaneously dosed in animals, but these models usually provide erroneous PK data primarily due to DDIs [29–31]. However, cassette dosing can help reduce the number of animals and samples

TABLE 18.4 Ideal “Drug-Like” Properties of Lead Candidates in Drug Discovery

Property	Ideal Range	Comment
<i>Physico-chemical</i>		
Molecular weight (Lipinski’s rule of five)	150–500 (CMC mean 349)	Exception: macrolide antibiotics with MW >500
Aqueous solubility	1–3 (CMC mean 2.5); a score >3 is considered as poorly soluble compound	1 = > 1 g/L; 2 = 0.1–1 g/L; 3 = 0.01–0.1 g/L; 4 = 0.001–0.1 g/L; 5 = < 0.001 g/L
Polar surface area	20–130 (CMC mean 75)	—
log <i>P</i> (Lipinski’s rule of five)	–0.7 to 5.0 (CMC mean 2.5)	—
Nonrotatable bonds	0–10 (CMC mean 5.56)	—
Number of hydrogen bond donors (Lipinski’s rule of five)	<5 (includes nitrogen or oxygen atoms with one or more hydrogen atoms)	—
Number of hydrogen bond acceptors (Lipinski’s rule of five)	<10 (includes nitrogen or oxygen atoms)	—
p <i>K</i> _a	Nonionized	Ionized compounds taken up via uptake transporter mechanisms may be accepted
Permeability (Caco-2)	100 nm/s	Some substrates of efflux transporters (e.g., p-glycoprotein) are poorly permeable that may require further investigation
<i>In vitro metabolism</i>		
Metabolic stability	100% stable	Variable and sometimes with several inactive metabolites and occasionally with active metabolites
CYP phenotyping	Identify polymorphic metabolism	Genetic screening in patients with appropriate dose adjustments may be required in some patients
<i>In vitro</i> and <i>in vivo</i> species comparison	No qualitative and quantitative differences in metabolism across species	This is often a major issue where significant species differences in metabolism may be found. MIST guidance document from FDA addresses on how to overcome these issues

(continued overleaf)

TABLE 18.4 (continued)

Property	Ideal Range	Comment
<i>In vitro</i> drug–drug interactions:		
CYP inhibition (competitive)	<1 μM	—
CYP inhibition (mechanism-based)	Not Applicable (NA)	—
CYP induction	Negative	Occasionally CYP induction may result in autoinduction of metabolism with loss of pharmacological activity. Dose adjustments may be required
Protein binding	<50%	10–99.9%
<i>In vitro</i> toxicology		
hERG channel inhibition	Negative	Cardiovascular toxicity due to drug–drug interactions with fatal arrhythmias (QT prolongation) is often an issue with poly pharmacy in geriatric patients
Ames mutagenicity	Negative	No threshold
<i>in vivo</i> bone marrow micronucleus	Negative	No threshold
Tolerability toxicology	Negative	Reversible toxicity is accepted if it is manageable without fatal consequences. Toxicity at high doses with wide therapeutic margin with relative to therapeutic dose
<i>in vivo</i> PK–PD		
Bioavailability	40–100%	—
PK–PD	Excellent efficacy in animal models with good correlation to pharmacokinetic properties	Many times, no acceptable animal models are available for measuring PK–PD correlations. Humanized animal models with genetic manipulation are increasingly becoming popular. A molecular biomarker that can relate to target engagement by potential drug candidate are also used in PK–PD modeling

for bioanalysis (cassette analysis of all compounds in the same sample) and increase the throughput in screening several compounds.

18.2.2.2 Physico-Chemical Properties. Several articles in the literature have reviewed physico-chemical properties of drugs that are favorable and provide optimal biological activity with minimal safety liabilities. Lipinski's "rule of five" has been very popular and considered as a guide by many medicinal chemists to synthesize molecules in drug discovery phase [32] and discussed elsewhere in this book in another chapter.

Ritchie and Macdonald [33] compared the aromatic ring count along with other drug-like properties (aqueous solubility, lipophilicity, serum albumin binding, and CYP and hERG inhibition) for their potential for developability as drugs. On the basis of their analysis, they concluded that three or less aromatic rings are better for developability of NCEs as drugs. Recent data by Ritchie *et al.* [34] indicate that increasing ring counts have detrimental effects on developability in the order of carboaromatics > heteroaromatics > carboaliphatics > heteroaliphatics (except for heteroaliphatics exerting a beneficial effect in certain cases). Increasing aromatic ring count also influence several developability parameters such as lipophilicity and molecular weight and contribute to poor oral bioavailability. They also suggested that fused aromatic systems may have a beneficial effect relative to their nonfused counterparts. Their analysis revealed that newer drugs have increased heteroaromatic rings than nonfused aromatic rings.

The physico-chemical properties that are considered most important during drug discovery process include solubility, polar surface area (PSA), ionization constant (pK_a), and lipophilicity ($\log P$).

18.2.2.2.1 Solubility. Although an ever-increasing number of NCEs exhibit poor aqueous solubility, the classical approach involves use of cellular and noncellular *in vitro* models that are deficient in their ability to accurately model the absorption of compounds. In many instances, poorly soluble drugs necessitate the inclusion of excipients to facilitate efficient delivery and enhance their bioavailability. Thus, there exists an increasing demand for *in vitro* models that can effectively evaluate the effects of excipients on permeability of NCEs [27,35,36]. Herein, we provide an overview of those solubility models currently in use and discuss their associated benefits and drawbacks. Furthermore, we review the challenges encountered in assaying the permeability of poorly soluble drugs and critically assess those experimental modifications and solutions employed thus far in terms of their capacity to generate results with accuracy and precision.

Methods for measurement of solubility in early discovery phase include kinetic and thermodynamic solubility. Kinetic solubility determination is carried out by spectrophotometry, turbidimetry, or nephelometry. Solubilities in simulated gastric fluid, simulated intestinal fluid (SIF) and fasting state SIF can be determined for selected compounds from the early discovery phase to assess its solubility in biological fluids *ex vivo*.

18.2.2.2.2 Ionization Constants (pK_a). During the discovery phase for NCEs as potential drug candidates, the determination of pK_a values can be valuable in the selection process [37–40]. Determination of dissociation constants for compounds capable of ionizing at various pH ranges can influence its solubility and absorption across the

GI tract. In humans, the pH of stomach is close to 2 and in the small intestine around 6 that can be affected by food [27].

Classically ionization constant (pK_a) is expressed using Henderson–Hasselbach equations, which can provide the extent of ionized versus unionized compound at a particular pH.

For acidic compounds: $pH = pK_a + \log([\text{ionized compound}]/[\text{unionized compound}])$

For basic compounds: $pH = pK_a + \log([\text{unionized compound}]/[\text{ionized compound}])$

The major problem for pK_a determination in drug discovery is poor solubility of compounds. Two different methods have been published in the recent years that employ cosolvents or surfactants. With the cosolvent approach, the solubility of some unionized molecules can be enhanced by mixing solvents such as methanol, dioxane, or acetonitrile with water (MDM). However, it has been observed that not all compounds dissolve in any one cosolvent–water mixture. Völgyi [37] investigated the four-component cosolvent system and showed that MDM dissolves the lipophilic compounds sufficiently and it can be used for compounds that are not soluble in methanol–water or other single organic cosolvent mixtures (e.g., 2-propanol, DMF, DMSO, and acetone). However, MDM also dissolves polar compounds so it can be considered as an efficient cosolvent for pK_a determination in drug research. Ravichandran *et al.* [38] argued that the cosolvent approach may result in erroneous pK_a determinations due to existence of two liquid boundaries, and the change in dielectric constant may lead to variation in the ionization behavior of the NCE. These investigators used nonionic surfactants such as Tween 80, CremophoreEL, or Labrasol to determine pK_a values of poorly soluble compounds. The solubilization occurs by entrapment of NCE molecule into micellar structure formed by the surfactant, which can entrap ionic, hydrophobic, and amphiphilic molecules.

pK_a determination using GLpKa:GLpKa is an automated instrument developed by Sirius analytical UK to determine the pK_a compounds [39]. The advantages of this instrument are that it requires very low amount of compound and consumes less time. pK_a determination by GLpKa can be performed by two methods, pH-metric method and spectrophotometric titration, for compounds with chromophore.

18.2.2.2.3 Polar Surface Area. The PSA of a molecule is an important physico-chemical parameter to predict its permeability and absorption into the body. It is defined as the surface area of nitrogen and oxygen atoms in a molecule plus the surface of the hydrogen atoms attached to these hetero-atoms. It has been established that a PSA value of over $140 \text{ \AA}^2$ usually yields molecules that are poorly absorbed from stomach and GI tract, whereas values below $60\text{--}70 \text{ \AA}^2$ suggest potential penetration of the blood–brain barrier, especially for central nervous system (CNS)-active drugs. PSAs can be calculated using several software, discussion on which is out of the scope for this chapter and is covered in another review [40].

18.2.2.2.4 Lipophilicity ($\log P$ and $\log D$). Compounds to permeate across biological membranes require certain balance of lipophilicity to hydrophilicity. Lipophilicity is inversely related to solubility, that is, the higher the lipophilicity, the lower the aqueous solubility. The balance between these two properties is very critical for compounds

TABLE 18.5 $\log D$ Values and Their Significance in Drug Permeability and Absorption for Orally Active Drugs

$\log D$ at pH 7.4	Significance for Drug Development
<0	Poor absorption across the GI tract and blood brain barrier. Susceptible for rapid renal clearance
0–1	A good balance between solubility and permeability. Good oral absorption but poor CNS permeability
1–3	Optimum range for oral absorption and CNS permeability. Low metabolic liabilities
3–5	Lower solubilities. High metabolic turnover
>5	Poor solubility and poor absorption across the GI tract. High metabolic turnover

to be absorbed from the GI tract. Relationship between $\log D$ and permeability across biological membranes is, however, nonlinear, permeation decreasing in both low and high end of $\log D$ values, and often a $\log D$ value of 5 is considered as an upper limit of desired lipophilicity (Table 18.5).

Frequently, NCEs synthesized in drug discovery are amphoteric molecules with both acidic and basic functional groups. Normal amphoteric molecules can undergo change from anion–neutral–cation depending on the pH. If specific ion-pair partitioning does not occur, only the neutral species of the three ionic states dissolves into the organic (octanol) phase. For such type of ampholytes, the relationship between $\log P$ and $\log P_{\text{app}}$ is given by the following equation:

$$\log P = \log P_{\text{app}} + \log(1 + 10^{\text{pH} - \text{p}K_{\text{a}}^1} + 10^{\text{p}K_{\text{a}}^2 - \text{pH}})$$

where $\text{p}K_{\text{a}}^1$ and $\text{p}K_{\text{a}}^2$ are the macro or stepwise protonation constants.

However, for amphoteric molecules with zwitterions coexisting in solution, the partition behavior is more complex. GLp K_{a} is an automated instrument developed by Sirius analytical UK to determine the $\log P$ or $\log D$ compounds [39]. This method is more advantageous and accurate as compared with the conventional shake-flask method.

18.2.2.3 Permeability and Drug Transport. For oral absorption, drugs from the GI tract should permeate the intestinal barriers and enter the portal blood circulation. Biomembranes comprise a lipid bilayer, with lipid layer interiorized and the hydrophilic end forming the surface. Interactions of membrane proteins at contact surface between single cells form tight junctions that form small aqueous pores. The number of these junctions depends on the cell or tissue type; for the small intestine, the area of aqueous pores amounts to about 0.01% of the whole surface. Compounds can cross biological membrane by two passive processes: transcellular (through the membrane) and paracellular (via the pore). As described in the chapter titled *Oral Absorption: from Physiology to Regulatory* in this volume, most compounds can be absorbed by the paracellular route, but the process is invariably slower than the transcellular; lipophilic compounds are rapidly absorbed by the transcellular route and hydrogen bonding acceptor–donor properties can affect permeation of drug candidates across the bilayer [41]. In addition,

many efflux and uptake drug transporters present in the intestinal tract influence the absorption of the drugs.

The assay tools routinely used in drug discovery for assessing permeability of NCEs include parallel artificial membrane permeability assay (PAMPA), human colon carcinoma cells (Caco-2) [42], Madin–Darby canine kidney (MDCK) cells, or LLC-PK1 cell line (derived from porcine renal epithelial cells). In early drug discovery, PAMPA and Caco-2 cells are more routinely employed [43]. If efflux of the NCE by P-glycoprotein (P-gp), BCRP, or MRP2 is suspected, then bidirectional permeability assays in Caco-2 cells or LLC-PK cells are performed. Alternatively, individually transfected MDCK cell lines with MDR1, BCRP, and MRP2 can be used to assess if any of these transporters are involved in the efflux of the NCEs.

18.2.2.4 Drug Metabolism and Drug–Drug Interactions. DM plays an important role in elimination/clearance of drugs, which in certain cases leads to generation of pharmacologically active metabolites. In certain cases, DM contributes to adverse events (AEs) that may be induced by reactive metabolites [44]. Drugs coadministered or food may lead to drug–drug/food interactions affecting the PK–PD and safety [45].

Other chapters in this Volume discuss chemical/biochemical interactions of various phase I and II enzymes that play a role in DM pathways. In the following sections, the impact of DDIs and reactive metabolites on drug discovery and development is discussed [46]. In addition, the evolution of drug metabolite identification using LC-MS/MS methods in the past decade is also described briefly.

18.2.2.4.1 Key Enzymes Involved in Drug Metabolism. Liver is the primary site of DM. However, extrahepatic sites of DM such as intestine, lungs, kidneys, bone marrow, and brain may be involved. The biological function of metabolic transformation is to increase the aqueous solubility of a drug to enable its excretion such that the drug does not cause toxicity to the body. Metabolism usually occurs via phase I and II pathways. The phase I metabolism occurs by introduction of polar groups via hydroxylation, dealkylation, and hetero-atom oxidation. If these phase I metabolites have adequate aqueous solubility, they can be excreted via bile and urine. The phase II metabolism occurs via conjugation reactions such as glucuronidation, sulfation, or glutathione conjugation. These conjugated metabolites have high aqueous solubility and are thus rapidly excreted. In certain cases, reactive drug metabolites form glutathione conjugates that are further processed to mercapturic acids before excretion [47].

CYP superfamily are a major class of drug-metabolizing enzymes that are involved in the metabolism of >90% of the drugs that are used clinically. CYPs are membrane bound enzymes and are primarily present in the endoplasmatic reticulum within the cell. The major human CYP enzymes involved in DM are CYP1A2, CYP2A6, CYP2B6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4. CYP2D6 and CYP3A4 contribute to the metabolism of ~20% and 50% of drugs currently in the market [48]. Microsomes also contain another phase I enzyme family known as *flavin mono-oxygenases* that predominantly catalyze the formation of sulfoxides and nitro-oxides [49]. Nonmicrosomal phase I enzymes that are involved in DM include monoamine oxidase (MAO), aldehyde oxidase, and xanthine oxidase [50]. MAOs are present in the mitochondria and are involved in oxidation of amines, while carbonyl reductases and alcohol and aldehyde dehydrogenases are cytosolic enzymes being involved in the oxidation of alcohols and aldehydes and in the

reduction of aldehydes and ketones. Aldehyde oxidase and xanthine oxidase, also known as *molybdo-flavor proteins*, primarily catalyze the oxidation of heterocyclic nitrogen-containing compounds, α -carbon adjacent to nitrogen atom.

Uridine diphosphoglucuronosyl transferases (UGTs) are the most prominent phase II enzymes present in microsomes [51]. Human UGT1A1, UGT1A6, and UGT2B7 are responsible for glucuronidation of majority of compounds prescribed. UGTs can catalyze the formation of *O*-, *N*-, and *S*-glucuronides and glucuronidation of carboxylic acids can result in highly reactive acyl-glucuronides.

Other important drug-metabolizing enzymes are peroxidases [52], including myeloperoxidase, eosinophil peroxidase, prostaglandin-H synthase [53], microsomal and soluble epoxide hydrolases, sulfotransferases, glutathione *S*-transferases, *N*-acetyltransferases, and methyltransferases. Peroxidases [52] can catalyze the formation of reactive free radical intermediates and have been implicated in bone marrow [54] and urinary bladder toxicities [55].

Genetic polymorphisms of many drug-metabolizing enzymes can contribute to interindividual variability in metabolism [56]. In some cases, the genetic polymorphism in CYPs resulted in toxicities in individuals with poor metabolism. The most widely studied enzyme with regard to polymorphisms is CYP2D6 followed by CYP3A4/5, CYP2C9, and CYP2C19. In selected cases, UGT polymorphisms have also been considered to be important for interindividual variability in metabolism and toxicity [57].

Another important matrix for the metabolism of drugs is blood compartment [58], of which serum esterases have been found to be the major contributors. These include cholinesterase, serum arylesterase, carboxylesterase, and red blood cell (RBC) esterases. These enzymes play a role in both activation of prodrugs and deactivation of drugs. Recent examples of marketed prodrugs are adefovir, tenofovir, valganciclovir, olmesartan, parecoxib, tamiflu, famciclovir, and ximelagatran [59].

18.2.2.4.2 Identification of Key Enzymes Involved in Drug Metabolism. *In vitro* studies on the metabolism of drugs are usually performed using liver preparations such as isolated perfused livers, liver slices, liver homogenates, isolated hepatocytes, subcellular liver fractions (S9, cytosol, and microsomes), or recombinant metabolizing enzymes overexpressed on nonexpressing cell systems, particularly CYP enzymes. Previously, identification of CYP enzymes was performed using three different methods, including use of (i) individual recombinant CYP enzymes, (ii) microsomes with specific CYP chemical inhibitors, and (iii) correlation analysis using at least 15 different individual microsomes characterized for individual CYP activities using specific probe substrates. The combination of all three methods was recommended for accurate identification of different CYP enzymes involved in DM [60,61]. FDA guidance, however, recommends using two methods in particular use of recombinant CYPs and chemical inhibition in human liver microsomes. Identification of key metabolizing enzymes can be performed by the use of human CYP enzymes derived from CYP transfected insect cells (supersomes and baculosomes) or bacteria (bactosomes) [62]. Use of individual recombinant enzymes may result in incomplete and inaccurate identification of CYP enzymes involved in DM for the following reasons:

1. Recombinant CYP enzymes in microsomes do not have the same micro-environment as in human liver microsomes and contain varying levels of redox partners such as CYP reductase, cytochrome b5, and phosphatidylcholine. Thus,

the catalytic properties of recombinant CYP enzymes do not exactly mimic the properties of CYP enzymes in human liver microsomes [63].

2. Many drugs are metabolized by more than one CYP enzyme. In such cases, the relative roles of CYP enzymes in DM can depend on the affinity (K_m) and capacity of individual CYP enzyme. For example, metabolism of drugs by CYP3A4 may occur by low affinity–high capacity, whereas CYP2D6-dependent metabolism of drugs may occur with high affinity–low capacity. Using individual recombinant enzymes thus lacks the competition between different enzymes and forces the metabolism of drugs yielding inaccurate results.
3. Recombinant enzymes are generated through deletion/modification of terminal sequence of individual CYP genes. This may also alter the catalytic properties of these enzymes relative to native enzymes present in human liver microsomes.

The chemical inhibition method of CYP phenotyping utilizes pooled (typically, 10–50 subjects) human liver microsomes in the presence of specific chemical inhibitors. For example, ketoconazole and quinidine are specific inhibitors of CYP3A4 and CYP2D6, respectively, at concentrations as low as 1 μM . Determination of the kinetic constants (K_m and V_{max}) for each metabolite is necessary as CYP enzymes have varying affinities and capacities to form drug metabolites. Thus, metabolite identification along with structural elucidation is required before carrying out chemical inhibition studies on NCEs. In addition to the chemical inhibitors, use of specific antibodies that block various CYP functions has been explored [64].

Some perplexing issues with CYP enzymes are their ability to catalyze atypical kinetic reactions that follow non-Michaelis–Menten kinetics [65] and include the following:

1. *Sigmoidal autoactivation*, in which the drug itself can activate its own metabolism as the concentrations are increased. Typical profile of these substrates show initial lag period in metabolism, but addition of more substrate increases metabolism rapidly in more than dose-proportional manner. Sigmoidal activation may also occur with the presence of other drugs in a concentration-dependent manner (hetero-tropic activation). Sigmoidal autoactivation should not be confused with CYP induction where the latter is dependent on drug-induced transcriptional activation of CYP genes (Section 18.2.2.4.4).
2. *Substrate inhibition* profile that is characterized by a decrease in velocity of metabolism as the concentration of drug is increased. It has been described by a two-site model in which one binding site is productive, whereas the other site is inhibitory and operable at high substrate concentrations, resulting in decreased velocity with increasing concentrations.
3. *Biphasic kinetic* profile that is characterized by an initial Michaelis–Menten-like increase in velocity with increasing substrate concentration. However, the profile does not become asymptotic, with the reaction profile eventually becoming linear with increasing substrate concentration. This results in the inability to predict an apparent V_{max} and thus apparent K_m [66].

18.2.2.4.3 Cytochrome P450 Inhibition and Drug–Drug Interactions. It is now well known that a drug can affect the metabolism of another drug, a concept known as

metabolic DDIs. Cases of this are plentiful and are discussed in detail elsewhere in this Volume. Since drug interactions often result in AEs, sometimes with fatal outcome, it is essential to screen NCEs in early drug discovery for their ability to inhibit, *in vitro*, the major CYP enzymes using human liver microsomes or human hepatocytes. Despite many CYP enzymes present in humans, five major CYPs (1A1/2, 2C9, 2C19, 2D6, and 3A4) account for the metabolism-related DDI issues for >90% of marketed drugs. Hence, the inhibition of the above five major CYP enzymes should be measured during early drug discovery process. Sometimes, one CYP enzyme may metabolize NCEs to metabolite(s), which may inhibit another CYP enzyme(s). Additionally, metabolism may also produce reactive metabolites that can irreversibly inactivate the CYP enzyme (e.g., troleandomycin inactivation of CYP3A4). This type of inhibition is known as *time-dependent* or *mechanism-based CYP inhibition*.

Current industry practice to assess CYP inhibition by NCEs is incubation of human liver microsomes with specific CYP probe substrates using LC-MS/MS. One tends to probe the metabolism-related DDIs of drug candidates by monitoring the impact of the test compounds on CYP metabolic activity using a known substrate. This is based on the assumption that whenever DDI occurs, regardless of the mechanism(s) involved (e.g., competitive, noncompetitive, or uncompetitive), the compound will interfere with the performance of a coadministered drug that is metabolized by the same enzyme [67,68]. Probe substrate inhibition assays for five of the major CYP enzymes [phenacetin for CYP1A2, diclofenac for CYP2C9, (*S*)-mephenytoin for CYP2C19, dextromethorphan for CYP2D6, and midazolam and testosterone for CYP3A4] in human liver microsomes are being used and metabolites of probe substrates are analyzed with rapid LC-MS/MS methods. The data generated can be plugged into a physiologically based pharmacokinetic (PBPK) model such as Simcyp (Section 18.2.4.2) and help in drug design in early discovery.

18.2.2.4.4 Cytochrome P450 Induction and Drug–Drug Interactions. Some CYP enzymes are regulated via soluble (cytosolic) or nuclear receptor activation. These receptors include Ah receptor for CYP1A1/2, pregnane X receptor (PXR) for CYP2C9, 2C19 & 3A4/5 and constitutive androstane receptor (CAR) for CYP2B and CYP2C induction. There are several excellent articles on this subject and thus this section is limited to highlight some of the concerns associated with CYP induction [69] which in certain cases may lead to reduction in therapeutic efficacy of co-medications. Some examples include: (i) rifampicin-mediated induction of CYP3A4 and increased clearance of oral contraceptives; (ii) carbamazepine induced CYP3A4 and increased clearance of benzodiazepines. Sometimes induction process may result in autoinduction of the test DM itself resulting in drug-resistance, following multiple doses of the same drug every day for two weeks. In some other cases autoinduction of metabolism may result in the increased formation of reactive metabolites [70]. Typically CYP1A1, 1A2, 2B6, 2C9, 2C19 are prone to induction in response to their gene activation by certain drugs. Interestingly, there are no reports on CYP2D6 induction to date, while phase-II enzymes like uridine diphosphate glucuronide (UDPG) have been reported to be induced by drugs.

The inductive effect of any drug on CYP enzymes can be evaluated using primary human hepatocytes. In the human liver, CYP3A4 is the most highly expressed CYP enzyme and is highly inducible by a wide variety of drugs. Induction of CYP3A4 can also have serious toxicological consequences as a result of increased DM that

contributes to DDI may lead to bioactivation of drugs to carcinogenic or toxic metabolites. Treatment of patients with prototypical CYP3A4 inducer rifampicin can lead to reduced plasma levels of the antidiabetic drug pioglitazone, leading to poor glycemic control in patient in which these medications are prescribed simultaneously. Upregulation of CYP3A4 can also exaggerate toxic responses to drugs as with rifampicin and acetaminophen coadministration.

The discovery of a family of nuclear receptors such as PXR [71], CAR and glucocorticoid receptor (GR) gives insight into the molecular explanation of CYP3A induction by xenobiotics. A stable hepatoma cell line expressing the human PXR and the CYP3A4 distal and proximal promoters plus the luciferase reporter gene can be used to assess the ability of a drug to induce CYP3A4 and CYP2B6. The mechanism of CYP3A4 induction is typically via activation of the PXR [72], resulting in activation of Retinoic X Receptor and formation of the hetero-dimer PXR–RXR complex. This hetero-dimer complex then binds to a response element in the CYP3A4 gene called the *PXR response element* [73,74].

18.2.2.4.5 Mechanism-Based Inhibition. Mechanism (or time) based enzyme inhibition is associated with irreversible or quasi-irreversible loss of enzyme function, requiring synthesis of new enzyme before activity is restored. The consequences of mechanism-based inhibition (MBI) are (i) auto-inhibition of the metabolic clearance of the inactivator itself and (ii) prolonged inhibition of the clearance of other drugs that share the same enzyme.

There may also be serious immuno-toxicological consequences if a reactive intermediate is covalently bound to the enzyme. The prediction of the *in vivo* consequences of mechanism-based enzyme inhibition requires estimates of the maximum inactivation rate constant (K_{inact}), the inactivator concentration associated with half K_{inact} (K_I), the concentration of the inactivator at the active site (I), and the first-order rate constant of the *in vivo* degradation of the enzyme (k_{deg}). Values of k_{inact} and K_I can be determined from appropriately designed *in vitro* studies.

MBI is a time-dependent as well as nicotinamide adenine dinucleotide phosphate (NADPH)- and concentration-dependent process, and in certain cases, drugs are converted by CYPs to reactive metabolites. The inactivation of CYP3A4 can be due to chemical modification of the heme, the protein, or both by covalent binding of modified heme to the protein [75]. Compared with reversible inhibition, MBI of CYP3A4 more frequently causes unfavorable DDI, as the inactivated CYP3A4 has to be replaced by newly synthesized CYP3A4 protein. DDI can lead to higher exposure of coadministered drugs, sometimes leading to toxicity. For these reasons, DM groups within pharmaceutical companies need a well-established screening assay to assess mechanism-based inactivation of major human CYP enzymes by new chemical substances that are being developed by the company [75].

The irreversible MBI of CYP3A4 refers to the inactivation of the enzyme via the formation of a metabolic intermediate that binds tightly and irreversibly or is covalently attached to the enzyme. At least three different mechanisms may lead to the inactivation of CYP during the metabolism of drug. The intermediate species can react irreversibly with nucleophilic amino acids in the active site or with the heme nitrogen atoms. A metabolite intermediate can also bind strongly to the heme iron to form a metabolite intermediate complex that does not actually destroy the CYP enzyme but renders it catalytically inactive. This is often described as quasi-irreversible inhibition. It is

believed that mechanism-based inhibitors may prove to be much more enzyme specific than reversible inhibitors [76].

Some of the criteria that are routinely used to determine whether a substrate is a mechanism-based inhibitor are as follows: (i) Loss of enzyme activity during preincubation must be time dependent. The enzyme activities, corrected for any loss of activity in the absence of an inhibitor, remaining after the preincubation should have a linear relationship to preincubation time. (ii) The inhibition requires that a cofactor, NADPH, is present and that metabolism is occurring due to NADPH dependence for electron transfer in the catalytic cycle of CYPs. (iii) The degree of inhibition should be concentration dependent with saturation kinetics. (iv) Inhibition should be irreversible and activity should not return on dialysis or gel filtration since the mechanism-based inhibitor should be covalently bound to the enzyme. Microsomes prepared from different cells overexpressing single human CYPs are now routinely used to investigate MBI of specific CYPs. These *in vitro* systems are commercially available and can be used to characterize time-, NADPH-, and concentration-dependent inhibition as well as to determine the enzyme kinetics parameters [77].

18.2.2.4.6 Concurrent CYP Inhibition and Induction: A Clinical Dilemma for Predicting DDI from *In vitro* Studies. The prediction of DDIs based on reversible CYP inhibition has been a standard part of preclinical programs in the pharmaceutical industry for many years [78]. This common practice has led to underprediction of the magnitude of DDI when the underlying inhibitory mechanism, including time-dependent inactivation (e.g., erythromycin and verapamil). Interestingly, some of these CYP inactivators are also potent competitive inhibitors and inducers of CYP3A4, further complicating the value of predictive tools. Although recent efforts have yielded methods whereby *in vitro* data can be used to provide accurate predictions of DDI arising via a time-dependent inactivation mechanism, it is important to acknowledge discrepancies that have been observed with some of the drugs tested, for example, cyclosporin, erythromycin, ethinyl estradiol, indinavir, mibefradil, oleandomycin, rifampicin, and verapamil [78]. These discrepancies may represent the mixed nature of the underlying mechanisms by which the precipitants interact with CYP3A4. These types of mixed inhibition–induction of the same CYP isoform can present challenges in the design of clinical DDI studies, which should be considered in early drug discovery process. In the recent years, *in vitro* hepatocyte models where both gene expression profiling using mRNA quantitation alongside CYP activity profiling are increasingly being used to understand the mixed inhibition–induction models in greater details.

18.2.3 Regulatory Considerations of Drug Metabolism and Drug Interaction Studies

Until the late 1990s, metabolic studies conducted by pharmaceutical industry were mainly restricted to use of radiolabeled NCEs for determining their ADME properties. There was lack of uniformity in conduct of metabolism studies by different pharmaceutical industries. In the late 1990s, FDA issued regulatory guidances that defined the role and practice of contemporary DM [79,80]. Since the publication of this guidance, DM has become integral part of drug discovery and development process [81]. In 2008, FDA published guidance entitled “Safety Testing of Drug Metabolites” [82]. This guideline gives an in-depth understanding of the metabolites to be analyzed in

preclinical and clinical studies. Table 18.6 gives a compiled list of regulatory guidance relevant to PK, DM and toxicity studies.

18.2.3.1 Safety of Metabolites. Conventionally, parent drug plasma concentrations have been used to assess systemic exposure to drugs in animals and humans. Adequate safety margin can be established based on the fold difference in exposure of parent in toxicological species compared with humans. Nonetheless, the main problem during drug discovery process is that no human data are available on species differences in DM and DT as related to their safety. *In vitro* studies using human liver microsomes or human hepatocytes can shed some light on potential human metabolites. However, when metabolites play a role in toxicity and if such metabolites are (i) present in humans (unique metabolite) but absent in toxicological species and (ii) if these metabolites have higher exposure levels in humans than in the toxicological species, then the safety of the metabolite(s) may not be adequately assessed in toxicity studies in animals. Pharmaceutical Research and Manufactures of America published a document entitled “Metabolites in Safety Testing” (MIST) [83]. This document provides a guideline to the pharmaceutical industry on the use of metabolite information in safety testing. The FDA guidance [82] emphasized that identification of unique human metabolite later in development could affect the progress of the molecule to registration.

LC-MS/MS advances have certainly become very useful in identifying potential human metabolites during drug discovery process. *In vitro* species comparison of metabolism in liver microsomes and hepatocytes including of human are very useful. Further studies *in vivo* in animal species can help address if there are any potential unique human metabolites that can contribute to safety issues later during clinical trials.

Some pharmaceutical companies are now conducting radiolabeled ADME studies early in drug discovery to avoid finding a unique human metabolite later in the development stage. FDA published guidance on the use of radiolabeled drugs in 2005 [84]. This guideline enlists the objectives of the use of radioactive drugs in human subjects to obtain basic information regarding DM. The purpose of such studies is not to determine safety and effectiveness of the drug. Tissue distribution studies in rats can provide the data to calculate the doses for use of radioactive drugs in human subjects.

18.2.3.2 Drug Interaction Studies. FDA’s guidance “Drug Metabolism/Drug Interaction Studies in the Drug Development Process: Studies *In vitro*” was issued in 1997 [80]. This regulatory document, for the first time, clearly defined the role of DM in the drug development. This document emphasizes the investigation of NCE metabolites together with its interaction with likely coadministered drugs during drug development. The primary site of metabolism, primary metabolic pathway, and the proportion of total clearance that each primary pathway contributes should be identified and elucidated. The FDA guidance for industry “Bioanalytical Method Validation” [85] provides guidelines for validation of LC-MS/MS assays to ensure uniformity across the scientific community. FDA suggests that decisions pertaining to selection of metabolites for testing for pharmacological activity or monitoring in humans should be made by the industry in consultation with regulatory agencies.

18.2.3.3 Drug Distribution. Distribution is the process by which a drug is transported in body fluids from the blood stream to the tissues of the body. A drug can be administered through a variety of routes, including intramuscular, intravenously,

^aAbbreviation: ICH, International Conference on Harmonization.

subcutaneously, orally, or topically (via dermal, nasal passages, ear, eye, etc.). After administration, a drug will distribute itself into all of the body's compartments and tissues that it is able to. The time it takes for this to occur is called the *distribution phase* and is usually rapid. A drug is said to be distributed into a theoretical volume, called the *volume of distribution* (V_d). The volume is usually measured in liter per kilogram (L/kg) and is considered theoretical because it is based on sampling drug concentrations immediately after dosing with the assumption that the drug is uniformly distributed throughout the body. Given that most drug targets are not in vascular space, access to target organs commonly relies on drug distribution. For example, for a drug to be active in the central nervous system, it must penetrate the blood–brain barrier.

The barriers for drug distribution to extravascular target organs include protein binding in systemic circulation as well as tissue uptake. Of course, metabolism and transport processes involved in hepatic elimination also represent a major barrier in tissue distribution. Since metabolism and transport have been discussed in other parts of this chapter, we will briefly discuss on the role of protein binding in drug disposition.

18.2.3.4 Plasma Protein Binding and Drug Disposition. The binding of a drug to plasma proteins enables the transport of drugs via the blood to target sites of action throughout the body. Only the fraction of drug unbound from plasma proteins is available to diffuse from the vascular system and accumulate in tissues, thereby enabling interaction with therapeutic targets and with drug clearance pathways. Therefore, the extent of drug binding to plasma proteins can have a significant impact on PK parameters such as clearance rates and volume of distribution. As the unbound drug is the fraction of the drug available to interact with therapeutic targets, the extent of protein binding can have significant effects on the pharmacodynamic (PD) properties of a compound. Among plasma proteins, human serum albumin and α -(1)-acid glycoprotein are the two most important proteins for binding of many drugs [86]. The static and dynamic topology of drug binding sites on these proteins, investigated by various spectroscopic techniques, X-ray crystallography, quantitative structure–activity relationships (QSARs), molecular modeling, photo affinity labeling, site-directed mutagenesis, and so on, has been reviewed elsewhere and not discussed here [87,88].

The physiological significance of *in vitro* plasma protein binding studies has always been debated. Several endogenous molecules, for example, free fatty acids, blood urea nitrogen, and bilirubin also bind to plasma proteins and compete with drug binding sites on plasma proteins. Changes in the endogenous molecule concentrations during pathological conditions, such as liver and kidney failure or various inflammation diseases, could significantly vary from person to person and may cause interindividual variation in protein binding of drugs [89]. However, the free fraction of the drug is usually assumed to be available for tissue distribution and in equilibrium with plasma compartment. Additionally, sometimes, drugs may partition into RBCs [90], which may complicate the interpretation of PK data.

Experimentally, drug plasma protein binding can be determined using equilibrium dialysis, ultrafiltration, or ultracentrifugation method [91]. Currently, more widely acceptable method to determine the plasma protein binding is considered to be equilibrium dialysis. Rapid Equilibrium Dialysis (RED) device (Thermo Scientific Pierce) and HTD 96 (Micro Equilibrium Dialysis from HTDialysis LLC) are the two, commercially available, high throughput 96-well formats used to determine the protein binding of drugs at discovery stage.

RED devices are more popular because of their unique advantage of achieving faster equilibrium. The RED device consists of disposable inserts and a base plate formatted to a standard microplate footprint [92]. Each single-use, disposable insert is made of two side-by-side chambers separated by a vertical cylinder of dialysis membrane (8K, 12K, or 25K molecular-weight cutoffs (MWCO)) validated for minimal nonspecific binding. This format requires no extensive assembly steps or specialized equipment, and each chamber or well is easily accessible from the top of the insert after insertion in the base plate. Additionally, the high surface-to-volume ratio of the membrane compartment allows rapid dialysis, where equilibrium can be reached in 4 h with high levels of reproducibility and accuracy. In many cases, experiments can be completed in >100 min. The RED device has been extensively validated for plasma-binding assays producing results consistent with those reported in the literature. The RED device offers significant improvements in automation, time requirements, versatility, and product reliability compared with other commercially available systems.

The HTD 96 device from HTDialysis has very easy setup. It can be assembled in minutes, easily cleaned, and is reusable. This also offers a wide selection of dialysis membranes. It is compatible with standard 96-well laboratory equipment and supplies. It requires 30–150 μL working volumes and has automation friendly design. A number of drugs have been analyzed using this device giving reproducible protein binding data [93].

18.2.4 Recent Advances in ADME Concepts and Related Technologies

During the past two decades, scientists from academia and pharmaceutical industry made several advances in understanding the drug absorption and dispositional characteristics. Especially, understanding the mechanisms of DM and DT made a major impact expanding into translational research for modern drug discovery.

18.2.4.1 Recent Advances in Clearance Concepts. The systemic clearance is representative of the elimination of the drug from the body. It is one of the important PK parameters that can help understand how the drug is cleared from the body. Physiologically, it represents the rate of elimination of a drug relative to the plasma concentration. The concept of clearance was originally proposed by Rowland and has been extremely useful for dosage adjustment because at the typical therapeutic doses, the systemic clearance of a drug is usually constant over the interval of plasma concentrations of clinical importance. This parameter is the one of the most relevant parameters in human efficacious and safe dose calculation from preclinical PK studies.

Clearance of the drug from the body depends on the intrinsic ability of the organs such as the liver and kidneys to metabolize or excrete. Also, clearance is a function of the blood flow rate (Q) to these organs. Clearance by definition represents the volume of blood cleared through an organ in unit time. To estimate clearance, the drug needs to give intravenously. Clearance cannot be estimated after an oral dose since the total dose does not reach the systemic circulation. The total clearance is evaluated from the PK data as shown in the following equation:

$$\text{CL} = \text{dose}/\text{AUC}$$

For certain drugs that get metabolized completely, renal clearance is negligible. In this case, systemic clearance can be approximated to hepatic clearance (CL_H) by liver. Hepatic clearance is given by

$$CL_H = Q_H * ER_H$$

where Q_H is the hepatic blood flow rate and ER_H is the hepatic extraction ratio. Hepatic clearance can be estimated approximately from *in vitro* intrinsic clearance (CL_{int}) data as shown in the following equation:

$$CL_{int} = V_{max}/K_m$$

where V_{max} is the maximum rate of metabolism and K_m the substrate concentration at half the maximum velocity (V_{max}).

With the recognition of the importance of drug transporters during the past decade, Kusuvara and Sugiyama [94] have developed a methodology to evaluate hepatic clearance measures with the addition of transporters, defined as follows:

$$CL_{int} = CL_{int,met} + PS_{int,bile}$$

where $PS_{int,bile}$ is the intrinsic efflux clearance of unbound drug into the bile, while $CL_{int,met}$ is the intrinsic metabolic clearance of unbound drug in the liver. Now the intrinsic organ clearance ($CL_{int,org}$) is given by

$$CL_{int,org} = \left[\frac{PS_{inf}}{PS_{eff} + CL_{int}} \right] \cdot CL_{int}$$

where PS_{inf} and PS_{eff} represent the intrinsic clearances for cellular uptake (influx) and efflux into the systemic circulation, respectively.

At the boundary condition where $CL_{int} \gg PS_{eff}$, that is, where the great majority of drug taken up by the hepatocytes is metabolized or excreted into bile, then $CL_{int,org}$ in the previous equation can be approximated by

$$CL_{int,org} = PS_{inf}$$

Above-mentioned equation seems to be consistent with the data presented for atorvastatin using isolated rat liver perfusion [95] and *in vivo* in rats [96] and humans [97,98], the results published using (i) multiple indicator dilution perfusion, (ii) *in vitro* rat hepatocyte uptake, (iii) *in vitro* rat liver microsome clearance data, and (iv) *in vivo* CL_{int} measurements demonstrated good *in vitro*–*in vivo* clearance correlations. They further predict *in vivo* human hepatic uptake clearance and suggest that these values approximate overall human intrinsic clearance measurements for statin drugs, including atorvastatin, pravastatin, pitavastatin, and fluvastatin. Benet further suggested that incorporating efflux transporter and metabolism inhibition data as well as studies where protein binding is changed should also be taken into equations above proposed by Kusuvara and Sugiyama [94]. For example, the $CL_{int,met}$ portion of Equation 18.8 proposed by Kusuvara and Sugiyama [94] is assumed to be independent of transport

processes and in all other treatments of intrinsic metabolic clearance. This was emphasized earlier in Equation 18.3 as proposed by Rowland *et al.* [99], where the partition coefficient between unbound concentration in the measured systemic circulation and that in the eliminating organ is assumed to be constant. However, inhibition, induction, or activation of transporters could potentially change this ratio so that in essence what we now call intrinsic metabolic clearance is not intrinsic, but rather varies with transporter changes. Studies with atorvastatin in humans [96] not only showed inhibition by rifampin of atorvastatin uptake (mediated by OATP1B) into the liver but also caused a change in the ratio of the atorvastatin lactone to the atorvastatin acid, thereby changing the amount of substrate available to the enzymes in the liver, since metabolism of atorvastatin by CYP3A4 occurs via the lactone, not the acid [100]. Thus, as we understand the biochemical and molecular mechanisms of drug disposition, the clearance concepts and equations need to be updated as we move along in the future.

18.2.4.2 Use of Simcyp in Predicting Human ADME. The simulation and prediction of human PK/PD using *in vitro* data from human tissues and animal models based on previous knowledge is becoming very important in preclinical drug development [101]. Even regulatory bodies, notably the US-FDA has a Critical Path Initiative that emphasizes the need for quantitative description of PK/PD for understanding the efficacy, safety, and dosing regimen design for any given drug candidate [102,103]. The success rate in drug development can be enhanced and also the cost incurred in this process can be reduced by the use of modeling and simulation tools. Simcyp (Simcyp Limited, Sheffield, UK) is one such commercially available tool.

ADME simulator [104], the Simcyp drug interaction prediction model, is a population-based PBPK model and considers the interplay among demographic (age, weight, height, sex, race, and disease), genetic, anatomical (organ size), physiological (blood flow, enzymes, transporters, plasma proteins, hematocrit, transit time, and pH), and drug-specific factors (molecular-weight (MW), pK_a , $\log P$, solubility, PSA, K_m , V_{max} , and f_u). Simcyp time-based models can be used to predict mechanism-based drug interactions of CYP3A [105]. The simulator combines the experimental ADME data generated routinely during preclinical drug discovery and development from *in vitro* enzyme and cellular systems and relevant physiochemical parameters of the compounds and dosage form with demographic, physiological, and genetic information on different patient populations to predict *in vivo* PK parameters and profiles. It predicts outcomes not just as “average” but across populations, allowing the characteristics of individuals at the extremes risk to be evaluated. Population-based simulator has also been used for identification of CYP enzymes involved in the metabolism of drugs (e.g., paroxetine) in humans [106]. Simcyp simulator can also be used for selection of alternative CYP3A4 probe substrates for clinical drug interaction studies using *in vitro* data and *in vivo* simulation [107]. PK modeling using Simcyp has also been utilized in understanding the role of UGT1A4 under CYP3A inhibited conditions in the metabolism of midazolam in samples from human clinical studies [108].

18.2.4.3 Biopharmaceutical Drug Disposition Classification System. Intestinal cells also contain drug metabolizing enzymes which can result in poor absorption of drug and metabolites entering the systemic circulation. Benet [109] introduced Biopharmaceutical drug disposition classification system (BDDCS) (Fig. 18.4) where he proposed that understanding the interplay between transporters and metabolism in

Figure 18.4 Biopharmaceutical drug disposition classification system (BDDCS), represents classification of the drugs into a four classes, based on drug solubility, permeability, metabolism, and drug transporters involved in the process of ADME. (See color insert.)

the intestine and liver is a very important determinant of drug disposition characteristics. According to this classification system, for highly soluble and highly permeable *class 1* compounds, metabolism is the major route of elimination. Transporters play a minor role in the intestine and liver. In contrast, for the poorly permeable *class 3 and 4* compounds, uptake transporters and perhaps efflux transporters could be important for drug elimination. Metabolism plays a minor role in drug elimination for class 3 and 4 drugs. Highly permeable, poorly soluble, and extensively metabolized *class 2* compounds present the most complicated relationship in defining the impact of transporters on drug disposition due to marked transporter–enzyme interplay. Uptake transporters are not important for bioavailability of class 2 drugs but can play a major role in hepatic and renal elimination. Efflux transporters have major effects on drug bioavailability, absorption, metabolism, and elimination of class 2 drugs. It is difficult to accurately characterize drugs in terms of the high permeability, that is, $\geq 90\%$ absorbed. The extensive metabolism may substitute for the high permeability characteristic. Thus, BDDCS may provide predictability in characterizing drug disposition profiles for all classes of compounds.

18.2.4.4 LC-MS/MS Advances in Pharmacokinetics and Drug Metabolism. In drug discovery, a quick assessment of drug concentrations require the development of rapid and accurate bioanalytical methods. Typically, bioanalytical groups support PK and TK studies, but in drug discovery, they also support a wide variety of *in vitro* studies, including *in vitro* metabolic stability, Caco-2 permeability, DDIs, and protein binding studies. Therefore, development of methods with higher throughput is very demanding in drug discovery programs [110,111]. Science of chromatography and

mass spectroscopy has rapidly advanced with detection levels of drugs and metabolites at femtomole and attomole levels. The advances in technology led to the development of LC/MS-based techniques in bioanalysis [112–116]. The elements of LC/MS applications ultimately owes the credit to the power of high performance liquid chromatography (HPLC) and ultra performance liquid chromatography (UPLC) to resolve the drugs and their metabolites using shorter run times (1–5 min) combined with the ability of MS to identify the drug molecules in the biological milieu at femtomole and attomole quantities. This integration of LC and MS effectively to quantitate the drugs at less than picogram levels has expedited the ADMET programs in the drug discovery process.

18.2.4.4.1 Quantitative Bioanalysis. The quantitation of drugs in biological matrices also requires efficient clean-up methods to exclude proteins and other endogenous molecules before analyzing the processed samples. This clean-up process should be such that 80% or higher levels of drug are recovered. Before analyzing drug concentrations in biological matrices, a quick and reliable bioanalytical method is needed with a calibration curve ranging from low nanomolar to high micromolar concentrations. This is one of the major problems because there is no prior biological data to decide on concentration ranges for calibration curve. Choosing an internal standard close to the structure without interfering multiple reaction monitoring (MRM) transitions is also required. The LC-MS-based *in vivo* PK screening approaches allow analysis of large number of samples with a throughput of up to 7000–10,000/month/instrument. In earlier times, a conventional set-up comprised single auto-sampler/HPLC column and MS systems in which one sample was injected at a time. The technological advances have allowed higher throughputs with rapid chromatography using UPLC, automated data processing, and sample pooling strategies (cassette dosing, dried blood spot analysis, etc.). The use of two auto samplers on two columns in parallel with a single triple quadrupole mass spectrometer, have led to reduction in HPLC/UPLC column equilibration time and common hold-ups associated with sample loading.

In early stages of drug discovery research, the bioanalysis allows rapid data generation so as to understand the PK properties of the NCE (along with its metabolites). Thus, in drug discovery, a bioanalyst develops a “fit-to-purpose” research method. In brief, the bioanalyst after receiving biological samples processes the samples quickly by protein precipitation and the supernatant is injected into LC-MS/MS system. The high resolving power of LCs and reverse phase columns and highly sensitive mass analyzers provide quick data that enable a pharmacokineticist to assess whether the NCE under test possesses favorable PK properties. Thus, LC-MS/MS techniques proved to be a cardinal in regular bioanalysis [117].

18.2.4.4.2 Metabolite Identification. Identification of metabolites and metabolic pathways (biotransformation) is essential during early drug discovery process to understand potential liabilities and risks associated with metabolites. Most common phase I and II metabolites screened for identification are shown in Table 18.7. Objectives of metabolite identification during drug discovery include the following:

1. Identification of metabolic soft and hot spots in an NCE and recommend medicinal chemists to design metabolically stable compounds. The soft spots include inactive polar metabolites that may be rapidly eliminated from the body. The hot spots include reactive intermediates (electrophiles and free radicals), which may

TABLE 18.7 List of Common Phase I and II Metabolites

covalently bind to tissue macromolecules (proteins/DNA) and/or cause oxidative stress resulting in toxicity or genotoxicity.

2. Identification of potential metabolites that have pharmacological activity. In such an event, a possibility of developing metabolite itself as a new drug can be explored.
3. Identification of species differences in metabolite profiles so as to explore occurrence of possible human metabolites and estimate their exposure in preclinical species. Recent FDA guidance [82] recommends identifying potential human metabolites as early as possible so that expensive and time-consuming toxicology studies with metabolites can be avoided if the metabolite exposures are covered in toxicology studies. *In vitro* studies using human liver microsomes and hepatocytes are often employed to identify potential human metabolites, preclinically.

Elucidation of the structure of many metabolites is not straightforward, especially when complex rearrangement leading to a unique metabolite and/or the formation of metabolites with isobaric molecular ions [118–122]. Recent advances in the LC-MS/MS technology allow detection of metabolites with high sensitivity—as low as femtomoles. LC with diode array detector is widely used to separate the mixture of metabolites and drugs, while MS serves as an ideal detector to identify the structure of metabolites [118]. In most cases, chromatogram obtained from diode array detector complements the mass chromatogram. Mass spectrometric detectors are more sensitive and robust compared with other detectors such as diode array detectors and nuclear magnetic resonance (NMR) spectroscopy. However, final confirmation of metabolite structure may need to be established using NMR spectroscopy. Different types of ion sources such as electrospray ionization (ESI), nano-ESI, and atmospheric pressure chemical ionization serves as interface between LC and MS and assist in the ionization of molecules.

18.2.4.4.3 Tandem Mass Spectrometers and Ion Trap Instruments in Metabolite Identification. Development of triple quadrupole mass spectrometers (tandem mass spectrometers) coupled with LC has made a significant impact in the metabolite identification research. Triple quadrupole instruments providing MS² fragmentation patterns are necessary to identify the metabolic soft spots [123,124]. To date, MRM mode remains to be the most sensitive method to confirm trace levels of circulating metabolites in biological fluids derived from animal or human ADME studies.

Recent technology such as triple quadrupole ion trap mass spectrometers where trap technology is integrated with triple quadrupole mass spectrometers is both sensitive and qualitative [125,126]. Triple quadrupole ion trap mass spectrometer coupled with LC is one of the ideal equipment to characterize the structures of metabolites. These instruments are more sensitive and provide MS² and MS³ fragmentation spectra of metabolites formed even in femtomole quantities and help characterize their structures. Apart from MS² and MS³ fragmentation spectra, neutral loss (NL) scans, precursor ion (PI) scans, and enhanced resolution (ER) scans from the trap instruments are characteristic to detect the metabolites. For example, NL scan of m/z 176 is used to identify phase II metabolites such as glucuronide conjugates. Other important and routinely screened glutathione adducts are identified by NL scan of m/z 129 and negative PI scans of m/z 272. ER scans are helpful in identifying the isotopic pattern of the metabolite structures. Apart from the above, combination of different scan modes such as enhanced mass-enhanced product ion (EMS-EPI), EMS-NL, EMS-PI, ER-EPI, and MRM-EPI scans with information-dependent acquisition have been effective tools in identifying the structure of metabolites. Recently, we have reported the importance of different scan modes in identifying the structure of metabolites using triple quadrupole ion trap mass spectrometer (API4000 Q-trap) coupled with LC. As an example, use of different scan modes such as EMS-EPI, NL-EPI, and PI-EPI scans has been successfully employed to confirm new metabolite of glyburide [119].

Accurate mass measurements (high resolution) in metabolite identification experiments can provide information that can distinguish isobaric molecular ions and correct fragmentation pattern. Higher versions of ion trap instruments such as orbitrap are capable of providing high resolution/high mass accuracy measurements of precursors and product ions regardless of relative ion abundance [127,128]. Orbitrap instruments also have the MS^{*n*} capabilities (i.e., acquisition of MS¹⁰ spectrum is possible, which are

highly useful in assigning the metabolic softspot in the molecule). Lim and coworkers have evaluated linear ion trap/orbitrap to identify the metabolites of carvedilol [118]. A total of 58 *in vitro* metabolites of carvedilol have been identified, which includes several glutathione conjugates. In this study, high resolving power and mass accuracies of instrument were utilized to obtain the chemical formula and structures of metabolites of carvedilol, including isobaric species with greater confidence. Mass accuracy of linear ion trap/orbitrap has been reported up to fifth decimal and this advantage has enabled differentiation of isobaric hydroxylated metabolites with greater confidence [118]. Orbitrap mass spectrometers are equipped to identify and characterize the structure of metabolites. Metabolites of nefazodone have been characterized using both quadrupole ion trap and linear ion trap/orbitrap. One research article describes the use of linear ion trap (LTQ)-Orbitrap for detection of nefazodone metabolites that allowed detection of isotopic pattern in which 28 metabolites of nefazodone were confirmed, while quadrupole ion trap could detect all the metabolites but had reduced quality of isotopic patterns that hindered metabolite confirmation [128].

18.2.4.4.4 Time-of-Flight Mass Spectrometers in Identification of Metabolites. Triple quadrupole-time-of-flight mass spectrometers (Q-TOF) with LC have been employed successfully for metabolite identification. In triple Q-TOF mass spectrometers, the ions of interest are mass selected in first quadrupole, followed by fragmentation in a second quadrupole or hexapole and analyzed by TOF detector. TOF detectors have high resolution and the ions of interest can be separated from isobaric molecular ions, thus facilitating the measurement of mass to charge (m/z) value of ions with an accuracy of 2 ppm [129]. For example, when a drug with ether functional group ($R-CH_2-O-CH_3$) is metabolized (i.e., O-demethylation followed by oxidation of alcohol) to acid ($R-COOH$), the molecular weight of the drug remains the same and if the fragmentation pattern of drug and metabolite is similar, the quadrupole resolution is not enough to differentiate them. In such cases, accurate mass measurements by TOF analyzers can differentiate the drug from metabolite and structures can be assigned. TOF analyzers can differentiate masses up to fourth decimal with precision and provides high mass accuracy for identification of the metabolites.

Rapidly developing mass spectrometric imaging technology has also been employed for metabolite identification directly in biological tissues [130–132]. Ion trap instruments with ionization sources such as matrix-assisted laser desorption ionization, desorption ESI, and direct analysis in real time coupled to LC have also been employed successfully to image the drug and metabolites.

18.2.5 Drug–Target Interactions and Pharmacodynamics

PD is the quantitative relationship between (observed) plasma and tissue concentrations of the active moiety and the magnitude of the (observed) pharmacological effect. A PK–PD model is a mathematical description of these relationships; the model parameters provide information about intrinsic drug properties. The knowledge of the combined PK–PD model and the parameter estimates allows prediction of concentration versus time ($c-t$) profiles and effect versus time ($E-t$) profiles for different dosing regimens. To understand the clinical significance of PK/PD modeling, it is important to realize that the observed $E-t$ profile of an individual patient depends on three main determinants: drug input, that is, dose, dose rate, and route of administration,

and intrinsic PK and intrinsic PD properties of the NCE. PK–PD modeling allows the scientist to simulate the concentration (or exposure) of NCE to the observed efficacy parameters that are clinically relevant. PK–PD evaluations in preclinical animal models help in obtaining a meaningful prediction of these parameters for human studies and to predict efficacious human dose. In addition, preclinical safety studies in animals can help determine the therapeutic margin between the safe dose and efficacious dose.

Generally, a biological “target” may be considered as the naturally existing cellular or molecular structure involved in the pathology of interest that the new drug to be discovered is meant to interact with and provide therapeutic action. Following administration of drug, it must reach the target tissue where the PD effect is anticipated. The target can be any biological molecule, including proteins (enzymes and receptors), nucleic acids (DNA, RNA, and gene), and ion channels. Many of the targets are macromolecules that specifically bind to the NCE and trigger the PD effect. The target compartment is assumed to be kinetically homogeneous, that is, concentration of the NCE is homogeneous and the drug–target interaction is instantaneous. The drug–target interaction is governed by the law of mass action. Hill [133] was the first to develop explicit mathematical model of simulated drug action to account for the time courses and concentration–effect curves obtained when nicotine was used to provoke contraction of the frog *rectus abdominis* muscle. According to the occupancy theory, the drug effect is a function of two processes:

1. Binding of drug to the receptor and drug-mediated activation of the target
2. Propagation of this initial target activation with a cascade of biomolecular events to the desired therapeutic effect, where the intensity of the therapeutic effect is proportional to the number of target sites occupied by drug

Depending on the disease indication, PD responses are measured as follows:

1. Clinical endpoints, for example, reduction in disease activity, survival, or cure
2. Surrogate endpoints, for example, blood pressure and progression free survival
3. Biomarkers, for example, cytokines, chemokines, inflammatory mediators, growth factors, transcriptional factors, and endogenous metabolites

These PD endpoints are currently being widely employed for understanding the PK–PD relationships early in drug discovery and development stages. As discussed earlier, despite extensive preclinical efficacy evaluations, the failures due to lack of efficacy in clinical phase II and III development is still a major problem. Several factors can be attributed to these failures, including

1. Lack of mechanistic understanding of the target and its contribution to disease pathogenesis
2. Species differences related to the target and associated biological effects
3. Inadequate understanding of PK–PD relationships at preclinical stages leading to errors in human efficacious and safe dose selection

Selection of preclinical animal model for efficacy evaluation has always been challenging. In majority of cases, only rodents (mouse and rat) are employed. Where species

differences in targets are noted, genetic manipulation of these animals is performed so as to knock-off the mouse target and knock-in the human target. However, if the biological effect triggered by target activation is different from humans, then translation of preclinical efficacy to clinical situation will be erroneous.

Interestingly, the regulatory guidelines for preclinical safety evaluation recommend use of a rodent and a nonrodent species. Among the nonrodent species, large animals such as dogs and nonhuman primates are most widely employed for safety assessment. In contrast, large animals such as dogs and nonhuman primates are rarely utilized for preclinical efficacy evaluation. Unfortunately, very little effort has ever gone into development of disease models in large animals, which can be attributed to one or more of the following reasons:

1. Difficulties in developing the disease models in larger animals.
2. Concerns regarding animal ethics in using large animals for research purposes.
3. The high costs involved in large animal disease modeling.

An interesting fact is that during drug discovery and development, >60% cost goes into clinical development. Thus, if a drug fails during phase II or III trials due to lack of efficacy, all the efforts put in developing the drug in terms of time and cost are futile. These facts warrant for a greater understanding of the pharmacology of NCEs at the early preclinical development stages and perhaps utilize more than one species, in particular large animals. In future, whether drug companies divest more efforts and resources at the preclinical development stages to avoid failures in clinical stages of drug development that too at the cost of huge losses remains to be seen. Table 18.8 shows all the preclinical DMPK and toxicology studies that are conducted before initiating first in man studies. Figure 18.5 proposes a rational and stepwise evaluation of efficacy and safety at drug discovery stages, using two or more different animal models and includes at least one large animal model, so as to reduce the late stage failures due to efficacy or safety issues.

18.2.6 Exploratory Toxicology During Drug Discovery

In the process of drug discovery, it is very important to evaluate the potential toxicological risks of a drug candidate as early as possible. The preclinical safety programs are aimed at understanding safety liabilities early in drug discovery and help in optimal design of good laboratory practice (GLP) toxicity studies so as to minimize the high rates of compound attrition during development.

Regulatory guidelines prescribe the investigation of safety in preclinical species for any NCE before it can be administered to man. These animal tests are intended to reveal potential toxicity associated with the candidate NCE and are conducted as a tiered program. The first studies conducted are referred to as *pilot studies*, preliminary studies, known as *dose range finding* studies, and these are used to select doses for subsequent regulatory studies. However, such studies require synthesis of several hundred grams of NCE and consume time. These studies are typically conducted as regulatory submission packages. However, by the time a toxicologist detects a problem or safety issue in a regulatory study, several months of time is lost in synthesizing sufficient quantities of the drug, conducting the regulatory study with a negative outcome. Thus, most pharmaceutical companies prefer integration of safety assessment measures into earlier

TABLE 18.8 List of Different DMPK and Toxicity Studies Conducted Before First-in-Man Studies

Hit	Hit to Lead	Lead Optimization	Preclinical Evaluation
Hit Identification	Tier 1 DMPK Assays (96- or 384-well assays)	Tier 2 DMPK-TOX Assays	Tier 3 DMPK-TOX Assays
Target identification	$\log D$, pK_a	Caco-2/MDCK transporters	PK evaluation using stable
Computational modeling	Kinetic solubility	Microsomal CYP inhibition (ic_{50} and K_i)	Polymorph/salts (mouse, rat, and dog)
Synthesis of NCE	PAMPA/Caco-2 assay	Microsomal time-based CYP inhibition (K_{inact})	CYP inhibition (K_i and K_{inact})
Lipinsky rule	Microsomal/RhCYP stability	CYP phenotyping (K_m/V_{max})	K_m/V_{max}
SAR	RhCYP inhibition (%)	CYP induction (activity assays)	Radiolabeled studies
Deuterated standards	Time-based RhCYP inhibition	Human hepatocytes	GLP genetic toxicology
Metabolite synthesis	RhCYP phenotyping	Metabolite ID	GLP safety pharmacology
Evaluation of biological potency and activity	Plasma protein binding	Reactive metabolite ID	MTD toxicity testing
Selection of hits	CYP induction (mRNA)	hERG channel assay	GLP two- to four-week toxicity testing
	Mouse, rat, dog, and monkey PK	Screening Ames assay	Allometric scaling
	Allometric scaling for predicting human PK	Screening micronucleus assay	Preclinical PK/PD
	<i>In vitro/in vivo</i> Pharmacological model POC	Toleration toxicity (one to two weeks)	First-in-human dose selection
	Preliminary PK–PD	Phospholipidosis Steatosis Cholestasis Cytotoxicity	

phases of drug discovery, which are called *tolerability toxicity studies*. These studies can also be part of investigative toxicology studies where a mechanistic basis of toxicity may be understood. The application of the FDA's Critical Path Initiative, a 2004 FDA white paper, *Innovation or Stagnation: Challenge and Opportunity on the Critical Path to New Medical Products* encourages pharmaceutical companies to conduct more investigative and mechanistic toxicology during drug discovery phase before it is too late.

Figure 18.5 Integration of pharmacodynamics, DMPK, and exploratory toxicology during early drug discovery. *Mouse, rat, monkey and dog and **rodent and large animal.

Exploratory toxicology is performed on NCE candidates with proven efficacy in animal models to assess any potential safety risks. Exploratory toxicology is one of the main phases of nonclinical toxicology assessment in which the NCE has to undergo a battery of *in vitro* and *in vivo* testing. The exploratory toxicity studies are typically not required to be reported to the regulatory agencies and need not be conducted according to the GLP guidelines. These studies allow early selection or rejection of compounds during early drug discovery stages, thereby saving time, effort, and expenditures. This process will help a medicinal chemist to synthesize better lead candidates devoid of potential safety liabilities. A variety of approaches are used, including *in silico* computational tools, applications of OMICS technologies (toxicogenomics), and some limited *in vitro* and *in vivo* tolerability toxicology studies. Some mechanistic data derived from toxicogenomics and other studies may help identifying potential safety biomarkers, which may be of clinical use during clinical trials.

18.2.6.1 Computational Toxicity Testing. As described earlier in Section 18.2.1, computational tools (Table 18.3) may be utilized early in drug discovery stages to design molecules that are devoid of any potential toxicity. *In silico* techniques for the prediction of toxicity have been developed since the late 1970s. These methods use computational approaches and are based on the structure of a compound. They are based on the principle that “structure defines activity and that the reaction of a chemical with a biological system is driven by its molecular structure.” *In silico* methods have the advantage that they can make fast predictions for a large set of compounds in a high throughput mode, predict even before the compound has been synthesized, and can therefore be used at a very early stage in the drug development process. There are two *in silico* methods used for the prediction of toxicity: QSAR and expert computer systems (e.g., DEREK, MultiCASE, and TOPKAT). QSAR means the quantitative relationship between a chemical structure and its biological/toxicological activity. QSAR models calculate the relationship between a chemical structure and their biological activity with the help of chemical descriptors that are generated from the

molecular structure. The expert computer systems predict the toxicity using different databases containing diverse chemical structures and their observed toxicity [134].

18.2.6.2 Tolerability Toxicity Studies. Tolerability studies are among these first tiered studies conducted in rodents and perhaps in dogs during lead optimization process of drug discovery. These tests are conducted to understand whether the drug has any specific safety issues near the pharmacological doses. These studies are often conducted with small number of animals with multiple doses for five to seven days. Such studies provide early indication of whether pharmacological doses are well tolerated. Any safety issues as an extension of pharmacology can be identified in these early studies. A safety issue related to pharmacological extension is usually a “class effect” where inhibiting or modulating a specific therapeutic target can result in serious adverse or toxic events. Such targets have very low potential for discovering therapeutically useful drugs where risks outweigh benefits.

Many times early investigative tolerability studies are limited to physical observations only. In some cases, these studies may include TKs, clinical chemistry, and histopathology assessment as well. These studies may also utilize novel technologies such as toxicogenomics and metabolomics for a mechanistic understanding of toxicity.

18.2.6.3 Toxicogenomics. Use of genomics to predict toxicity of NCEs is based on the principle that drugs induce a multitude of complex molecular perturbations involving differential gene expression at the transcriptional and translational level, leading to toxic outcomes. The data for changes in gene expression caused by a NCE under test can be used to identify its potential to cause toxicity at lower doses or at earlier time points. The application of this gene-expression profiling technology to toxicology is called *toxicogenomics* [135]. The advantages of the toxicogenomic approach include increased sensitivity, low variability, reduced number of animals, and lower compound requirements. The limitations of these tools are (i) variability of gene expression from tissue to tissue, (ii) necessity of relevant databases, and (iii) systems that are expensive to run and maintain [136,137]. Another disadvantage of this tool is the generation of large amounts of data that can be cumbersome to analyze and interpret.

18.2.6.4 Genotoxicity Assays. The genotoxicity assays are used to determine the potential of a NCE to cause DNA damage that may lead to an increased incidence of tumors or birth defects through heritable effects in the germ cells. Genetic toxicology is generally positioned as part of the drug safety or toxicology function during preclinical stages of drug discovery. Assessment of genetic toxicity involves subjecting the test NCE to a defined battery of genotoxicity tests. This battery of tests generally includes a bacterial mutagenesis assay (Ames test), an *in vitro* cytogenetics assay, and an *in vivo* cytogenetics assay (micronucleus assay).

These genotoxicity assays for any test compound are carried out according to the guidelines prescribed by International Conference of Harmonization (ICH), as well as GLP guidelines and generally require multigram quantities of compound. Genotoxicity testing was historically relegated to the later stages of drug development. However, the need for earlier testing was apparent to drug companies that experienced termination of a drug's development when unacceptable genotoxicity was discovered during the regulatory submission stage, up to which point huge monetary, personnel, and,

most importantly, time resources had been expended. Today, it is possible to measure standard mutagenic and clastogenic endpoints with as little as 5–30 mg of compound, allowing genotoxicity screening to be conducted much earlier in drug discovery stages.

Among the more widely used scaled-down genotoxicity screening assays are a miniaturized version of the Ames bacterial mutagenesis assay and an *in vitro* micronucleus (IVMN) assay.

18.2.6.4.1 Mini (Screening) Ames Genotoxicity Assay. The bacterial reverse mutation assay (Ames test) with *Salmonella typhimurium* is a well-established assay to identify the chemicals that can produce gene mutations [138]. The Ames test typically uses five strains of *Salmonella* with preexisting mutations that render the bacteria unable to synthesize the essential amino acid histidine and are unable to grow in histidine-free medium. The chemicals that induce mutations on these particular genes restore gene function and allow the cells to synthesize histidine and therefore grow in its absence, therefore called *reverse mutation assay*. A disadvantage of this test is that it is time consuming, expensive, and requires higher quantities of compound. Flammann *et al.* [139] miniaturized the Ames test for the screening of pharmaceuticals and required smaller quantities of the test compound as compared with the conventional Ames test. The mini-Ames is performed in microwell plates using two *Salmonella* strains, TA98 and TA100. TA98 detects frameshifts and TA100 detects base substitutions leading to missense mutations. Whereas the original Ames test is carried out by plating bacteria onto selective agar plates, the mini-Ames is carried out in liquid culture using 96-well plates. The bacterial plates are incubated with the test compounds for 72 h, after which bacterial growth is measured spectrophotometrically using a pH indicator that changes color in response to the acidification of the media due to bacterial growth. Compounds can be tested in both bacterial strains with and without S9, at different concentrations along with reference compounds. The advantages of mini Ames includes small amount of compound requirement and rapid turnaround time. The major limitation of these miniaturized versions of the Ames test lies in the impossibility to work with all the five strains used in the regular Ames test [140].

18.2.6.4.2 In vitro Micronucleus Assay. The IVMN assay is a widely used screening test, which shows a high level of concordance with regulatory chromosomal aberration assays [141]. Micronuclei are chromatin-containing bodies that represent fragments or even whole chromosomes that were not incorporated into a daughter cell nucleus at mitosis. The purpose of the assay is to detect agents that induce chromosome damage leading to the induction of micronuclei in interphase cells. The agents that induce micronuclei include clastogens (through interaction with the DNA) or aneugens (through interference with the spindle apparatus). The major mechanisms responsible for micronucleus induction are double DNA strand breaks leading to micronuclei with acentric fragments [142].

The IVMN assay is a simple and rapid method routinely used as a prescreening test for the quick assessment of *in vitro* chromosomal aberration, which is part of the recommended regulatory battery of tests for genotoxicity testing. It can also detect aneuploid-inducing agents, which are difficult to detect with the *in vitro* chromosomal aberration assay.

The IVMN assay is conducted in chinese hamster ovary (CHO-K1) cells seeded in multiwell plates and treated with the test compounds for 24 h without S9 and for 3 h

with S9. Cytochalasin B is added after 24 h and the cells are incubated for an additional 24 h, after which the cells are fixed and scored for micronuclei under the microscope.

18.2.6.5 hERG Binding Assay. The hERG encodes the inward rectifying voltage gated potassium channel in the heart (IKr), which is involved in cardiac repolarization. Inhibition of the hERG current causes QT interval prolongation resulting in potentially fatal ventricular tachyarrhythmia called *torsade de pointes*. The hERG potassium channel is expressed in the mammalian heart and is crucial for repolarization and relaxation of cardiac muscle during every heartbeat. Human mutations of this gene increase susceptibility to QT-interval prolongation on an electrocardiogram (ECG). This prolonged interval can lead to lethal ventricular arrhythmias. A diversity of drugs from widely differing chemical scaffolds block this channel.

Much attention recently has been focused on identifying the drugs that prolong the QT interval. It is imperative to investigate any NCE for its potential to adversely prolong repolarization before its first use in man. To reduce the risk of failure of a drug candidate in preclinical safety studies due to QT prolongation, it is important to screen compounds for activity on hERG channels early in the lead optimization process. A number of *in vitro* and *in vivo* hERG assays are available. There are four broad categories of *in vitro* models: overexpression of human hERG channel on human embryonic kidney cells (HEK293), mouse fibroblasts and Chinese hamster ovary cells, isolated tissues such as canine mid-myocardium and Purkinje fibers, and the isolated intact (Langendorff-perfused guinea pig or rabbit) hearts [143]. Multilead ECG recordings in conscious or anesthetized guinea pigs, rabbits, dogs, or pigs comprise some *in vivo* models for testing effects of the candidate drug on QT prolongation [144].

Current regulatory guidelines consider hERG assays a major component of an integrated cardiac risk assessment that takes into account chemical class of the compound, assay sensitivity and specificity, and potency of test compound in repolarization assays in comparison to reference compounds [145].

18.2.6.6 Phospholipidosis. Phospholipidosis is a lysosomal storage disorder characterized by excessive accumulation of intracellular phospholipids in tissues such as liver, kidney, and lung [146]. The drugs that induce phospholipidosis are known to contain both hydrophobic and hydrophilic cationic domains called *cationic amphiphilic drugs*. These include antibacterials, antipsychotics, antidepressants, antianginals, anti-malarials, antiarrhythmics, and cholesterol-lowering agents [147]. Several mechanisms have been proposed for drug-induced phospholipidosis, including inhibition of the enzymatic activity of phospholipidases and binding of the drug to the phospholipid to form drug–phospholipid complexes that cannot be broken down by phospholipidases [148].

Phospholipidosis does not necessarily constitute toxicity, and can resolve by itself, but it is predictive of drug or metabolite accumulation in affected tissues that have led to liver, kidney, or respiratory failure. Depending on the type and number of tissues affected, phospholipidosis occurrence in test animals can raise safety issues, which may be critical for the risk assessment. Consequently, phospholipidosis is of concern to the FDA, which in 2004 formed the FDA Phospholipidosis Working Group to study the problem and recommend strategies for phospholipidosis screening studies [149]. Safety profiling of potential phospholipidosis-inducing drugs early in the drug

discovery phases can help in impediments in the progress of the candidate drug to the later phases of drug development.

To detect the phospholipidosis induction in drug discovery phase, various *in vitro* methods have been developed and used as phospholipidosis screening assays. These include use of fluorescent dyes (e.g., Nile red) or fluorescently labeled phospholipids (e.g., 1-acyl-2-[12-(7-nitro-2,1,3-benzoxadiazol-4-yl)amino-dodecanoyl]-sn-glycerol-3-phosphocholine) in cell culture.

18.2.6.7 Cytotoxicity Assays. Cytotoxicity is simply the quality of any NCE for being toxic to the cells, regardless of the mechanism. Cytotoxic compounds can be either developed as a therapeutic that targets rapidly dividing cancer cells, or in case of a different therapeutic indication, cytotoxic compounds can be identified and excluded during initial high throughput screens for unwanted cytotoxic effects before they are selected for further development. Several mechanisms may be involved in cytotoxicity of a given NCE. These mechanisms include inhibition of mitochondrial pore transition [148], covalent binding to cellular macromolecules [149], induction of oxidative stress via free radicals [150], or alteration of cell cycle phases [151]. Many of these cell-damaging events may lead to apoptotic or necrotic cell death.

It is interesting that cellular glutathione (GSH) plays a vital role in protecting the cell from reactive metabolite damage. In many cases, the reactive metabolites covalently bind to proteins, but cellular GSH can prevent such damage and protect the cells. Alternatively, cellular GSH may also protect from free radical-mediated damage by scavenging the free radical metabolites of drugs. However, in this process, thiyl radicals of GSH may induce formation of oxygen radical and increase in cytotoxic events [152].

There are various types of *in vitro* assays used to detect the cytotoxicity. Examples of a couple of widely used methods are described below.

Cell death causes damage to the integrity of the cell membrane, which can be measured by the cytoplasmic enzyme activity released by damaged cells. Lactate dehydrogenase is a stable cytoplasmic enzyme present in all cells. It is rapidly released into the cell culture supernatant on damage of the plasma membrane [153]. Adenosine triphosphate (ATP) that is present in all metabolically active cells can be determined in a bioluminescent measurement [154,155].

Another method is based on colorimetric principle that relies on the metabolic activity of viable cells, which reduces tetrazolium salts [e.g., 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, commonly known as *MTT*] to a blue formazan or alamar blue that converts to resorufin [156].

18.2.6.8 Other *In vitro* Mechanism-Based Toxicity Assays. These include use of *in vitro* models to examine the mechanisms underlying actions of chemicals on organs or tissues observed *in vivo*. The *in vitro* models are designed to elucidate possible mechanisms of drug toxicity and their relevance to the target organs. The test NCE is delivered directly to the cells and the changes in viability or other functional parameters measured. Table 18.9 gives examples of test systems and their potential to predict their potential to cause toxicity.

Thus, current trend of including toxicology earlier in the discovery phase permits identification of unsafe compounds in the initial preclinical phase and thus allows for early withdrawal of bad actors and provides the opportunity to turn a potentially harmful compound into a successful one. Exploratory toxicology improves the quality

TABLE 18.9 *In vitro* Test Systems and Their Potential to Predict Different Toxicities

Test System, Example	Prediction
Primary hepatocyte culture	Hepatotoxicity including phospholipidosis and cholestasis
Tissue slices/organ components liver or kidney	Hepatotoxicity/nephrotoxicity
Bone marrow cell cultures	Hematopoietic toxicities
Whole embryo culture	Predict teratogenicity
Fertilized chicken eggs	Corrosion and irritancy
hERG assay	Cardiotoxicity
Langherhan's cells	Immunotoxicity
Ames and micronucleus assays	Genotoxicity

and quantity of drugs entering clinical studies. It enhances the safety and efficacy of new compounds and allows compounds to be prioritized early in the development process.

18.3 ROLE OF TRANSLATIONAL RESEARCH AND BIOMARKERS IN DRUG DISCOVERY AND DEVELOPMENT

Translational medicine refers to the meaningful transition of a NCE found to be effective preclinically, for use as a therapeutic in humans [157]. Translational PK–PD modeling involves integration of *in silico*, *in vitro*, and *in vivo* preclinical data with mechanism-based models to anticipate the effects of new drugs in humans. Translational models hold promise to facilitate design and/or selection of lead compounds, selection of first-in-human dose early clinical trial design, and POC studies of NCEs. Mechanism-based PK–PD modeling aims at the prediction of exposure–response relationships in humans, including their inherent intra- and interindividual variability. Exposure is expressed as time course of drug concentration in plasma, whereas response is expressed as the time course of drug-effect intensity. Mechanism-based PK–PD models contain specific expressions to quantitatively characterize processes on the causal path between plasma concentration and effect. Prediction of efficacy in humans based on the efficacy data in the animal models is challenging and there is need for mechanism-based biomarkers that allow building POC [158]. In addition, predicting safety challenges in clinic makes use of information from genomics, proteomics, and metabonomic data sources [13,159]. Biomarkers can be defined as quantifiable physiological or biochemical marker, which is sensitive to intervention or drug treatment. A safety biomarker is a treatment-emergent finding that substitutes for or translates into a clinically relevant adverse outcome. In case of cardiovascular safety evaluation, the two biomarkers that have been used for any drug candidate are assessment of (i) left ventricular ejection fraction by either echocardiography or multi-gated acquisition scan and (ii) electrophysiological measurement of QT/QTc duration, assessed by ECG, for predicting risk of a potentially fatal arrhythmia called *torsades de pointes* [160]. Biomarkers are represented by diverse parameters such as (i) serum parameters (e.g., the primary product of an enzyme, which is inhibited by the drug), (ii) disease severity (e.g., C-reactive protein (CRP) and other markers in inflammatory processes), (iii) imaging (e.g., plaque morphology in drugs affecting atherosclerosis,

liver fat content as safety biomarker, or positron emission tomography) [156,159]. The successful use of PK–PD modeling and biomarker data is dependent on (i) selection of mechanism-based biomarkers and its link with clinical endpoint, (ii) quantification of drug/metabolites in biological fluids under GLP conditions, (iii) GLP-like assay methods for biomarkers, (iv) mechanism-based PK–PD modeling and validation [161]. Unless a biomarker is validated, it is not acceptable to regulatory agencies as surrogate endpoint for determination of drug's efficacy. Biomarker selection and validation are important processes that ensure the successful application of the biomarkers in drug discovery and development.

18.3.1 Success Stories of PK–PD Evaluation in Humans from Preclinical Studies

PD studies in animal models of disease allow extensive evaluation of a number of disease parameters and biomarkers. These data from preclinical studies together with PK evaluation allow establishment of meaningful PK–PD relationships. The preclinical PK–PD data are instrumental in validating chosen biomarker that can then be employed in POC studies in humans. A few examples of application of the preclinical PK–PD data, which has successfully allowed meaningful PK–PD evaluation in humans, are discussed below.

Efavirenz (Sustiva), an anti-HIV drug, was found to cause necrosis of the renal proximal tubular epithelium in rats after an oral dose of 700 mg/kg. This renal toxicity was not observed when efavirenz was dosed in cynomolgus monkeys or humans. The nephrotoxicity in rats was attributed to the formation of a glutathione adduct that was further found to be a mixture of cysteine–glycine and cysteine adducts [162]. Mechanistic studies with labeled efavirenz and coadministration with acivicin, a g-glutamyltranspeptidase inhibitor, confirmed that the formation of the glutathione conjugate and its processing finally to the cysteine conjugate was necessary for eliciting the nephrotoxicity in rats. This glutathione conjugation pathway was missing in cynomolgus monkey or in humans. This species-specific pathway and its absence in humans, followed by detailed mechanistic studies, helped place this issue in the proper perspective in terms of risk to patients. It was concluded that the nephrotoxicity in rat observed at high doses was not a safety concern for humans.

The relationship between PK and PD can also be utilized for optimal dose selection. Efalizumab, a recombinant humanized monoclonal IgG1 antibody, was found to be efficacious for the treatment of moderate to severe chronic plaque psoriasis. Efalizumab, a targeted inhibitor of T cell interactions, binds to the CD11a subunit of lymphocyte function-associated antigen 1 (LFA-1), thereby preventing LFA-1 binding to intercellular adhesion molecule 1. The PK and PD data from the efalizumab clinical development program were utilized to select of the optimal weekly subcutaneous dose of efalizumab (1.0 mg/kg) in adults [163].

Katz and coworkers proposed the use of LXR-623, a novel liver X-receptor agonist in atherosclerosis. They proposed that enhancing reverse cholesterol transport via the upregulation of cholesterol transporters such as the ATP-binding cassettes ABCA1 and ABCG1 could inhibit the progression of atherosclerosis. The authors found that LXR activation resulted in a dose-dependent increase in ABCA1 and ABCG1 expression [164].

Angus and coworkers made an attempt to rationalize the dosage of artesunate in patients with acute falciparum malaria. An inhibitory sigmoidal maximum effect ($E_{\max}$)

PD model typical of a dose–response curve was fitted to the relationship between dose and shortening of parasite clearance time (PCT). The $E_{\max}$ was estimated to be 28.6 mg/kg as an oral dose, and the 50% effective concentration was 1.6 mg/kg of body weight. They concluded that there was no reduction in PCT with the use of single doses of artesunate higher than 2 mg/kg, and therefore reflects the average lower limit of the maximally effective dose. This PK–PD relationship prevented the need to conduct highly expensive and long clinical studies [165].

Olsen *et al.* [166] used PK–PD modeling as a tool to predict the therapeutically effective plasma levels of antipsychotics. They predicted therapeutically effective steady-state plasma levels by means of conditioned avoidance response behavior in rodents and correlated it with clinically relevant plasma exposure for the classical antipsychotic drug haloperidol and four second-generation antipsychotics: sertindole, clozapine, risperidone, and olanzapine. The authors established the PK–PD relationship by modeling the time–response and time–plasma concentration data. Overall, a good correlation was observed between the rat dopamine D_2 receptor occupancy levels providing 50% response in the conditioned avoidance response test and the dopamine D_2 receptor occupancy levels reported from responding schizophrenic patients treated with antipsychotics. The proposed PK–PD model could act as a guide for determining effective plasma concentrations of potential antipsychotics in the clinical setting. This would hence accelerate the overall drug development process.

18.3.2 Current Gaps in Predicting PK–PD in Humans from Preclinical Studies

There are numerous challenges in the conduct and implementation of PK–PD data. The first major concern is that plasma concentrations may not necessarily reflect the concentrations of a drug at the site of action. This leads to lack of correlation between plasma concentrations and the drug effect leading to hysteresis or proteresis loops that can be resolved using indirect link models. To precisely describe the concentration–effect relationships, complicated PK–PD models have been proposed that require a thorough understanding of multiple receptors, presence of active metabolites, partial agonists, agonist/antagonist relationships, presence of endogenous agonists or antagonists, baseline effects, and baseline characterization. There is always a risk of development of tolerance that may be due to downregulation of receptors or change in the sensitivity of receptors. This may lead to tachyphylaxis and is an example of proteresis loop. This kind of tolerance has been observed with morphine. On the contrary, there may be sensitization or upregulation of receptors as that seen with cortisol and adrenocortico tropic hormone (ACTH) that would require more sophisticated modeling techniques to build a PK–PD correlation [167]. Other factors that affect the PD evaluation include status or disease state and genetic and environmental differences, which render establishment of a PK–PD correlation difficult. The most challenging aspect of PK–PD modeling is the correlation of PK–PD model with safety or efficacy outcomes. This involves a detailed knowledge of pathophysiology of disease and its progression. Data for disease progression in case of chronic diseases come from epidemiological studies that may not cover the underlying factors that play a role in the disease pathophysiology. For instance, in cardiovascular disease, the mortality outcomes have been correlated to a decrease in cholesterol levels or decrease in systolic and diastolic blood pressure. In contrast, both these endpoints are favorable outcomes and cannot be correlated to death in patients as an endpoint.

Likewise, in case of anti-HIV agents, some correlation has been observed between viral load and efficacy [168]. Such gaps that remain represent challenges to effective use of PK–PD correlations and their successful application in drug development.

18.3.3 Impact of OMICS and Other Novel Technologies on Future of PK–PD Assessment in Preclinical and Clinical Trials

The disciplines evolving from the sequencing of the human genome (genomics), transcriptomics [169], proteomics [170], and metabonomics [171,172] have the potential to facilitate drug discovery, but the greatest value lies in the integration of these diverse technologies. “Metabonomics” refers to the quantitative measurement of the dynamic multiparametric metabolic response of living systems to pathophysiological stimuli or genetic modification. It does not measure the metabolism of the compound itself but rather looks at the pattern of change in hundreds or thousands of endogenous biomolecules, which forms the “fingerprint” of efficacy or toxicity. Metabolomics is used for the metabolic regulation and fluxes in individual cells or cell types and the measurement thereof. Metabonomics data compliment gene expression and proteomic data. Metabonomics can provide information on a whole organism’s functional integrity over time after drug exposure. Metabonomics data can facilitate early *in vivo* toxicological testing, lead compound selection, prelead optimization, and *in vivo* toxicological testing. During development, the data can find new preclinical and clinical safety biomarkers and mechanisms and allow for metabotyping and the validation of animal models against human disease profiles [173]. Advances in “omics” technologies (genomics, transcriptomics, proteomics, and metabonomics) were touted as having the potential to revolutionize our approach to disease diagnosis, prognostication, and development of novel therapeutics. However, whether the “omics” can hold the promise of rapid advances in medicine “from the lab bench to the bedside” remains to be seen [174]. Although great progress has been made in this area, understanding processes such as disease progression (or drug response) requires systematic insight into dynamic (and temporal) differences in gene regulation, interaction, and function. Thus, an integration of these technologies with the PK and PD would fasten the path of drug development. In fact, the number of new drugs (NCEs) or biologics submissions to the FDA and other regulatory agencies worldwide has decreased significantly over the past decade. Current costs of taking an NCE to market has increased to nearly \$1 billion [175], which represents a barrier to investment in innovative therapeutics, particularly those with limited market value or diseases, which affect third-world or economically challenged populations. Today, the identification of disease-related genes and pathways is fundamental to drug-discovery programs. Although the sequence of the human genome is known, we have names/functions for only 15–20% of the ca. 32,000 genes. Till date, almost all the genes indicated for human hereditary (monogenic) diseases have been identified; however, the greater challenge will be to unravel the polygenic disease phenotypes and/or multifactorial diseases. Bioinformatics represents a novel way to expand our knowledge of diseases, link genotypes to phenotypes, unravel polygenetic disease causality, and identify new therapeutic targets. Application of these technologies should provide insight into the mechanistic basis for the disease pathobiology. The fine structure mapping aided by single nucleotide polymorphisms (SNPs) can provide a more detailed analysis. It is because of their dense distribution across the genome that SNPs are viewed as ideal markers for large-scale genome-wide

association studies to discover genes in a number of common complex diseases. High throughput SNP analysis technologies, which can analyze thousands of SNPs in large sample sets, provide an excellent tool for use in genetic association studies. Another area where SNP technology has a great impact is in pharmacogenomics, where genetic markers that predict response to therapeutic agents are sought. Pharmacogenetic approaches can aid the designing of strategies for reducing side effects of drugs, particularly for a percentage of the population prone to AEs. SNPs have also contributed to resolve safety issues as in the case of the HIV drug Abacavir that had exhibited hypersensitivity reactions in ~4% of the population receiving the drug post marketing. In case of HIV disease management, viral load and resistance genotyping has helped in adopting appropriate treatment regimens for the patients [176]. The application of genomics can contribute throughout the drug development process from initial discovery all the way through life-cycle management. The current most widely used technique for the study of gene-expression patterns on a genomic scale is DNA microarray. Microarrays allow for the simultaneous measurement of changes in the levels of thousands of messenger RNAs within a single experiment.

Systems biology is the analysis of relationships between a biological system and its response to genetic or environmental stimuli. Technically, systems biology involves modeling and simulating the complex dynamic interactions between genes, transcripts, proteins, metabolites, and cells using integrated systems-based approaches. It encompasses many of the “omic” technologies described above and uses computational and mathematical models to analyze and simulate networks or pathways. It also takes into account spatial and temporal relationships that give rise to cause and effect in biological systems. One approach is the development of “therapeutic engineering,” which is the application of the principles of mathematics, engineering, physics, chemistry, and biology to better understand human pharmacology, physiology, toxicology, and pathophysiology. Computational therapeutics or *in silico* pharmacology is concerned with the development of techniques for using software to collect, manipulate, and link biological and medical data. In current times, there is a costly, but bridgeable, gap in understanding processes such as disease progression (or drug response), which requires insight into dynamic (and temporal) differences in gene regulation, interaction, and function. There is a need to have fusion between mathematical modeling, informatics, and disease understanding to make the leap to effective acute and preventative care (effective total disease management). Use of the “omic” technologies can help facilitate the detection, diagnosis, and management of therapy. Therefore, the application of these technologies provides hope to allow accurate disease monitoring and paves way for improving treatment strategies so as to reduce patient morbidity and mortality in the coming future.

18.4 SUMMARY

Drug development is a sequential process from discovery to preclinical development, through clinical drug development and beyond. PK assessment involves *in vitro* testing during discovery stage, followed by preclinical development with substantial animal work, next clinical phase I in healthy volunteers, followed by phase II and III in patients with target disease. The role of PK, PD, and metabolism from an industry perspective is to allow rational selection of candidate compounds that can be taken forward for development as a therapeutic that can be used to treat patients through desired

route of administration. Modern drug research strategy for early discovery to late-stage development is to develop and utilize validated *in vitro* assay methodologies and *in vivo* animal models that are predictive of human ADME, efficacy, and safety. PK/PD analysis, modeling, and simulation is becoming increasingly important in drug labeling due to its potential for predicting drug behavior in populations that may be difficult to study in adequate numbers during drug development and its value in optimizing clinical trial designs. The ability to correlate drug effects and model these during the drug development value chain, from mechanistic studies in preclinical models, biomarkers in phase I, surrogate markers in phase II, and clinical endpoints in phase III are key to the success of any new drug research program.
